ABSTRACT: We examined bacterial colonization of transparent exopolymeric particles (TEP) in nutrient-manipulated mesocosms subjected to different turbulence intensities. We quantified heterotrophic bacterial abundance, production and diversity using fluorescence *in situ* hybridization (FISH). The abundance of attached bacteria increased significantly with TEP size in all treatments. The slope values of the number of bacteria scaled with TEP size varied from 1.15 on Day 1 to 2.04 on Day 11 in still and turbulent tanks, respectively. Comparison between these slopes indicated that the number of attached bacteria for a given TEP diameter was higher under turbulence. The addition of nutrients and turbulence in mesocosms neither supported higher bacterial abundance nor resulted in a correlation between bacterial concentrations and TEP. However, in enriched turbulent tanks, the number of attached bacteria was higher and was linked to rapid TEP formation after the diatom bloom. This was accompanied by higher bacterial production ($1.21 \mu\text{mol C l}^{-1} \text{d}^{-1}$ at the intermediate level of turbulence on Day 9), which was positively related to TEP. These correlations highlight the finding that higher bacterial productivity was due to a larger fraction of attached bacteria (up to 56.4%). Changes in bacterial production occurred with simultaneous changes in the community structure, i.e. the percentages of the *Cytophaga-Flavobacteria-Bacteroides* cluster increased significantly. By Day 9, this cluster became the dominant group of bacteria attached to TEP (85 and 90%, respectively at intermediate and high levels of turbulence). Among the marine heterotrophic bacterioplankton, this phylum is known to be common as attached bacteria. Therefore, it seems that the added nutrients and subsequent TEP production can be used by bacteria more efficiently under turbulent conditions through a shift in group-specific composition towards more attached bacteria with higher production rates.

INTRODUCTION

A large portion of organic matter in the marine environment is processed in the microbial loop through heterotrophic bacteria. Bacterioplankton thus play a central role in biogeochemical cycling, not only in the cycling of carbon, but also in the cycling of elements that limit phytoplankton growth (Azam et al. 1983).

Pelagic microorganisms inhabit a strongly structured aquatic environment characterized by a continuum of organic matter composed of colloids (Wells & Goldberg 1994), submicrometer particles (Koike et al. 1990) and other detrital particles of various chemical compositions and sizes, which are present in high concentrations in seawater (Alldredge et al. 1993, Verdugo et al. 2004). Among these particles are transparent exopoly-

*Email: pedrotti@obs-vlfr.fr

meric particles (TEP), which are enriched in carbon relative to nitrogen or phosphorus, and appear to be a key element in the fluxes of organic matter in coastal and oceanic ecosystems (Mari et al. 2001, Engel et al. 2004).

TEP constitute a suitable site for bacterial colonization (Passow & Alldredge 1994). In marine pelagic environments, the number of bacteria colonizing TEP varies from 5 to 40%, and in some cases 89% of the total bacterial numbers (Passow & Alldredge 1994, Schuster & Herndl 1995, Mari & Kjørboe 1996). Bacteria themselves may act in the formation of TEP by secreting polysaccharides as free exopolymers or capsular material (Stoderegger & Herndl 1998). Also, the high hydrolytic enzyme activity of bacteria in aggregates, including TEP, suggests their degradation and/or consumption by bacteria that mediate the transformation of particulate organic matter to a dissolved phase (Smith et al. 1992, Smith et al. 1995, Radic et al. 2006). These processes do not only account for the higher bacterial activity of aggregates but are also responsible for the observed difference in the composition between attached and free-living bacterial communities in marine and freshwater systems (DeLong et al. 1993, Knoll et al. 2001, Simon et al. 2002).

Several factors such as nutrient supply, phytoplankton, grazers and viruses are known to affect the structure and activities of bacterial communities (Riemann et al. 2000). Theoretical and experimental studies have shown that small-scale turbulence strongly influences the structure of pelagic food webs by changing the phytoplankton diffusion layer (Mann & Lazier 1996), nutrient dynamics and fluxes to osmotrophic organisms (Karp-Boss et al. 1996). Although bacteria are below the theoretical size limit in which eddy motion can directly enhance production (Lazier & Mann 1989), this view is changing, as organisms 1000× smaller than the Kolmogorov microscale may be affected by some residual inertial motion (Hill et al. 1992). It has been suggested that turbulent mixing influences motility and microspatial distribution of marine bacteria due to chemotactic behavior and physiological responses of bacteria (Bowen et al. 1993, Seymour et al. 2000). Turbulence may also directly or indirectly affect bacterial dynamics, activity and mortality (Dolan et al. 2003, Malits et al. 2004). Malits et al. (2004) showed that small-scale turbulence could directly affect bacterial communities by increasing bacterial size and altering bacterial morphology. Turbulence may also indirectly affect bacterial abundance, growth and respiration through food web interactions (Peters et al. 2002, Bergstedt et al. 2004).

According to Pinhassi et al. (2004), changes in bacterioplankton species composition are dependent on a dominant phytoplankton group and also on turbu-

lence. Furthermore, turbulence affects the dynamics of suspended particles by increasing collision and coagulation rates (Kjørboe 1997). The newly released colloidal organic matter coagulates much faster under turbulence than under still conditions (Stoderegger & Herndl 1999). Turbulence promotes TEP aggregation, and depending on its intensity, modulates carbon export by maintaining the TEP pool at the surface or enhancing sedimentation (Beauvais et al. 2006). It is thus of primary importance in furthering our understanding of pelagic systems to determine how bacteria interact with organic matter and conversely, in what way the structure and complexity of the organic matter influence bacterial distribution.

Here we report on the bacterial colonization of TEP in mesocosms under different turbulence intensities and nutrient conditions. TEP dynamics and phytoplankton responses from this experiment have been reported elsewhere (Beauvais et al. 2006). The characterization of the bacterial communities employed fluorescent *in situ* hybridization (FISH) techniques, which have been successfully applied to detrital particles (Lemarchand et al. 2006). In this study, we set out to investigate (1) bacterial colonization of transparent exopolymeric particles (TEP), (2) the role of TEP as an organic substrate for bacteria, (3) the influence of turbulence on changing substrate availability for bacteria and (4) whether these changes are accompanied by comparable changes in the composition and activity of particle-associated bacteria.

MATERIALS AND METHODS

Study site and sampling. The mesocosm experiment was carried out at the Marine Biological Field Station (Espeland, Norway) from July 10 to 25, 2001 in the framework of the European NTAP program (Nutrient dynamics mediated through turbulence and plankton interactions). The mesocosms consisted of 12 on-land cylindrical polyethylene tanks (2.6 m³, 1.5 m diameter, 1.5 m depth) filled with postbloom seawater from 5 m depth of the Raunefjorden fjord. The subsurface water was screened through a 250 µm mesh nylon netting to remove most metazoan grazers (see Beauvais et al. 2006 for details). For the analyses of attached bacteria, 6 mesocosms were sampled.

The tanks were divided into 2 treatment series: one series received no nutrients (T tanks) while the other series was fertilized on Day 1 (NT tanks). The nutrient addition (16 µM N:1 µM P:32 µM Si) followed the Redfield ratio. In both treatments, tanks were exposed to different turbulence intensities: 5×10^{-2} to 8×10^{-2} (T2 and NT2) and $1 \text{ cm}^2 \text{ s}^{-3}$ (T4 and NT4). Two sets of mesocosms were not subjected to artificial turbulence

(still mesocosms: T0 and NT0) where the energy dissipation rate measured was $2 \times 10^{-5} \text{ cm}^2 \text{ s}^{-3}$. The measured dissipation rates are in the range of realistic levels of turbulence found in the euphotic zone, notably in coastal areas (MacKenzie & Leggett 1993). Turbulence was generated using vertically oscillating grids placed at a depth of 1 m and with a vertical stroke of 40 cm in order to create nearly homogeneous conditions. Each grid consisted of a steel frame that was covered with Teflon and 2 Plexiglas grids (10 cm opening, 5 cm grid width) attached to it. An acoustic Doppler flow meter was used to measure water velocity and turbulent kinetic energy. Dissipation rates in $\text{cm}^2 \text{ s}^{-3}$ were calculated from energy spectra using a linear regression method (Stiansen & Sundby 2001).

Integrated samples were taken every other day from each mesocosm using Plexiglas tubes (5 cm diameter, 1.5 m depth), at 09:00 h. Subsamples were collected for the determination of suspended chl *a*, TEP and for bacterial analysis. The chl *a* concentration was analyzed fluorimetrically on 90% acetone extracts (Parsons et al. 1984).

TEP determination and bacterial colonization of TEP. Water samples for TEP determination and bacterial colonization were collected every second day. Samples (5 to 10 ml) were fixed with 2% formaldehyde and gently filtered through 0.2 μm white Nuclepore filters. TEP and bacteria retained on the filter were stained with 500 μl of an aqueous solution of 0.06% acetic acid (pH 2.5) and 0.02% Alcian blue 8GX. Filters were mounted on a white Cyto-Clear slide (Logan et al. 1994) after double staining with DAPI. This technique allows direct observations of TEP and bacteria on the filter. Slides were stored at -20°C in the dark until analysis using an Axiophot-Zeiss epifluorescence microscope. Pictures were captured with a CCD color video camera (752 \times 582 pixels resolution, 0.08 lux minimum sensitivity). Two pictures of a unique field were taken simultaneously at 630 \times magnification, one under UV light to count total bacteria, and the other under transmission light to observe TEP. For each filter, an average of 500 bacteria and 70 ind. TEP were counted and sized.

The TEP perimeter was traced semi-automatically and the equivalent spherical diameter (ESD) of an individual TEP was then calculated from area measurements assuming the symmetry of a sphere. Counts were binned by ESD into 12 logarithmic size classes between 1 and 56 μm . Attached bacteria were counted by overlaying the 2 pictures (at 630 \times magnification) for direct and simultaneous visualization of free and TEP-attached bacteria. We also estimated the fraction of free-living bacteria retained beneath or on TEP during filtration. The number of retained bacteria represented $2.8 \pm 1.3\%$ of the total bacterial count (1 to 6%; $n = 51$). Considering the low values, this fraction was not

included in the calculations. Two replicate filters were counted. For each sample, the relationship between the number of attached bacteria per TEP (n) and the size of the TEP was calculated. The number of attached bacteria was fitted to a power law function, $n = ad^b$, where d is the equivalent spherical TEP diameter, and a and b are constants for a given sample. The constants were obtained from log-log plots of n vs. d . TEP concentration was given in $\# \text{ ml}^{-1}$ and carbon content (TEP-C, $\mu\text{g C ml}^{-1}$) was determined from the size-frequency distribution using the size-dependent relationship proposed by Mari (1999):

$$\text{TEP-C} = 0.25 \sum_i n_i r_i^{2.55} \quad (1)$$

where n_i is the concentration of particles in size class i , and r_i is the TEP radius (μm) for the same size class.

Calculation of the fraction of TEP-attached bacteria. The magnification (630 \times) used to count TEP and bacteria simultaneously may underestimate both large TEP and small bacteria. Thus, the fraction of total TEP-attached bacteria to the total bacterial count in different treatments was calculated according to Passow & Alldredge (1994) by combining (1) the general relationship between the number of attached bacteria per TEP (n) and the size of the TEP ($n = ad^b$) as described in previous section, (2) total bacterial counts (obtained using 0.2 μm DAPI filters at 1000 \times magnification) as described in the following section, and (3) the size distribution of TEP determined by Beauvais et al. (2006) for the same experiment. Beauvais et al. (2006) counted a minimum of 600 TEP for each sample at 3 successive magnifications (100 \times , 200 \times , 400 \times) to cover the entire size spectra.

We also estimated the 'encounter rate kernel' of bacteria with TEP based on the model of Kiørboe et al. (2002) for bacterial colonization of aggregates. The volume of water from which the TEP collected bacteria per unit time (B , also called encounter probability rate, in terms of $\text{cm}^3 \text{ TEP}^{-1} \text{ s}^{-1}$) was calculated as:

$$B = 4 \times \pi \times D \times r_{\text{TEP}} \times \text{Sh} \quad (2)$$

where D is the diffusion coefficient of bacteria, r is the TEP radius and Sh is the Sherwood number. We used a diffusion coefficient of $0.4 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$, as estimated by Kiørboe et al. (2002) for a marine bacterium. The Sh value in the absence of advection is 1. According to Kiørboe et al. (2002), colonizing bacteria detach from aggregates after relatively short residence times, so we assumed 1 h as the residence time of bacteria colonizing TEP prior to detachment. B was calculated for each of the 12 size classes of TEP, and TEP concentration was normalized (TEP ml^{-1}) for each specific size class. Results are the predicted number of bacteria attached for each TEP size class per ml for each treatment and sampling day.

Bacterial abundance and heterotrophic production.

Water samples for bacterial abundance and production were collected every second day. Total bacterial abundance was determined by direct counting. Water samples (5 ml) were preserved with 2% (wt/vol) formaldehyde, stained with DAPI (final concentration, $0.25 \mu\text{g ml}^{-1}$) for 5 min, and filtered onto black $0.2 \mu\text{m}$ polycarbonate filters (Porter & Feig 1980). Between 500 and 600 bacteria were counted with an Axiophot-Zeiss epifluorescence microscope at $1000\times$ magnification. Heterotrophic bacterial production was measured by the incorporation of tritiated leucine in bacterial protein synthesis according to Kirchman et al. (1985). The samples were incubated in the dark at *in situ* temperatures with $60 \text{ nM } [^3\text{H}]\text{leucine}$ (Amersham, SA) for 1 h, after which production was stopped by the addition of 100% trichloroacetic acid (TCA). Samples were stored in a refrigerator prior to counting in a Packard Tri Carb liquid scintillation analyzer (model 1900 A). Results were expressed as incorporation of leucine ($\mu\text{mol C l}^{-1} \text{ d}^{-1}$), with the theoretical conversion factor of $3.1 \text{ kg C mol}^{-1}$ being used to convert leucine incorporation rates to bacterial carbon production (Simon & Azam 1989).

Fluorescent *in situ* hybridization. The composition of the total bacterial community was determined on Days 0, 1, 2, 3, 5, and 9 by using FISH. Bacterial cells from 10 to 40 ml subsamples were fixed with 2% formalin, filtered onto $0.2 \mu\text{m}$ white polycarbonate membrane filters (47 mm diameter), and stored at -20°C . On Day 9, the community of TEP-attached bacteria was also studied. Bacterial cells were filtered onto $0.2 \mu\text{m}$ polycarbonate filters (25 mm diameter), stained with Alcian blue, and hybridized using different probes. Experiments showed that it is possible to combine TEP techniques and FISH probes; counts of positive cells before and after staining filters with Alcian blue did not differ.

The probes used were ARCH915 for Archaea and EUB338 for Eubacteria (Amann et al. 1990). The group-specific probes for the detection of the Alpha, Beta and Gamma subclasses of Proteobacteria were ALF968, BET42a and GAM42a, and CF319 to detect members of the *Cytophaga-Flavobacterium* cluster of phylum CFB. A negative probe (Non 338) was used as negative control. Probes BET42a and GAM42a were used with a competitor oligonucleotide. Probes were labeled with the indocarbocyanine fluorescent dye CY3 (Interactiva). Hybridization, washing and DAPI staining procedures were adapted from Ouverney & Fuhrman (2000) and Pernthaler et al. (2001). The hybridization buffer contained 0.9 M NaCl, 20 mM Tris-Cl, 10% dextran sulphate, 0.01% polyadenylic acid, 0.2% bovine serum albumin, and 0.01% sodium dodecyl sulphate (SDS), and was used with a variable concentration of formamide. Hybridization was per-

formed at 46°C for 3 to 4 h, with a probe concentration of $5 \text{ ng } \mu\text{l}^{-1}$. Filters were then incubated in a washing buffer composed of 20 mM Tris-HCl, a variable concentration of NaCl, 5 mM EDTA and a SDS solution, at 48°C for 10 to 15 min in the dark. Filters were then stained with DAPI and mounted in a 4:1 mixture of Citifluor and Vecta Shield on glass slides. Counting was performed using a Zeiss epifluorescence microscope equipped with appropriate filter sets. On the same filter, at least 500 DAPI-stained cells were counted under UV light and CY3-positive cells were counted under green light. For filters stained with Alcian blue on Day 9, attached bacteria stained with the specific probes were counted by switching between green light to visualize probe-labeled bacteria and visible light to count TEP.

Statistical analysis. Two-way ANOVA was used to test for significant differences in (1) the colonization rate of TEP between treatments, (2) the abundance of total bacteria between treatments, and (3) the relative abundance of Eubacteria between treatments. Total numbers of cells and the percentage of TEP-attached cells in treatments were analyzed using nutrient and turbulence as fixed factors. A 2-way factorial covariance analysis (ANCOVA) for independent samples was used to test the effect of nutrients and turbulence on the slopes of regression lines between the number of attached bacteria (dependent variable) and the size of the TEP (concomitant variable). This was done for each sampling day (except Day 9). Statistical significance was accepted for $p < 0.05$. To determine the significance of the coefficient of determination (r^2), a *t*-test according to Fisher was performed. Potential relationships of TEP with bacterial abundance (total and attached) and bacterial production were tested using Pearson's correlation coefficient or linear regression.

RESULTS

TEP abundance and bacterial colonization

In non-enriched tanks, TEP occurred at low concentrations ($<3.5 \times 10^4 \text{ ml}^{-1}$) with no apparent temporal patterns (Fig. 1A). In nutrient-enriched tanks, TEP concentrations remained low until Day 3, then increased exponentially to reach $34 \times 10^4 \text{ TEP ml}^{-1}$ on Day 11 at the highest level of turbulence (NT4, Fig. 1A). In these tanks, the highest TEP concentration occurred subsequent to the diatom bloom as shown by the increase in the ratio of chl *a* ($>10 \mu\text{m}$) to total chl *a* (Fig. 1 B) (see Beauvais et al. 2006 for more details on TEP dynamics and phytoplankton responses in this experiment).

Fig. 1. (A) Transparent exopolymer particles (TEP) concentration (# TEP × 10⁴ ml⁻¹) in different mesocosms. (B) Ratio of chl a (>10 μm) to total chlorophyll in different mesocosms. For details of experimental conditions see 'Materials and methods', 'Study site and sampling'

Double-staining TEP with Alcian blue and DAPI indicated that bacteria commonly colonized particles. An average of 80 ± 15% of TEP was colonized by bacteria with no significant differences between treatments (ANOVA; $F = 2.42$, $p = 0.10$, $N = 35$). The absolute number of bacteria attached to TEP (range: 1 to 60 bacteria TEP⁻¹) increased significantly with TEP size, as described by a power law relationship, with bacterial numbers being scaled with TEP diameter raised to an exponent of 1.15 on Day 1 in still tanks

(NT0) and an exponent of up to 2.04 on Day 11 in turbulent tanks (T4) (average: 1.64 ± 0.2). All regressions in all treatments were highly significant ($p < 0.001$) (Table 1, Fig. 2). The abundance of attached bacteria in the different treatments was compared by testing for differences in the regression lines relating the number of bacteria per TEP and the ESD of the particles for each treatment. At the beginning of the experiment and on Day 7, no significant differences were observed between treatments (ANCOVA, ns; Table 2). However, on Days 3, 5 and 11, the number of attached bacteria was significantly higher under turbulence (ANCOVA; $F = 6.69$, 30 and 5.22; $p = 0.001$, 4.5×10^{-13} and 0.005 for Days 3, 5 and 11, respectively), although the abundance of attached bacteria was not affected by the addition of nutrients (ANCOVA, ns). At the end of the experiment (Day 11), there was also a significant interaction between the 2 factors (nutrients and turbulence), suggesting that the effect of turbulence on attached bacteria was dependent on nutrient addition (ANCOVA; $F = 3.86$, $p = 0.02$). In still tanks (T0 and NT0) and in non-enriched tanks (T2, T4), the numbers of attached bacteria did not differ significantly between the 2 levels of turbulence, whereas regression slopes in enriched turbulent tanks showed that higher numbers of attached bacteria were reached at the highest turbulence level (NT4; Table 1). Using the regressions we calculated the expected number of bacteria attached to 1 TEP (Fig. 2). We found that for a given diameter of TEP, bacterial colonization was higher under turbulence. For example, the average number of bacteria per TEP at an ESD of 10 μm varies from 5 to 15 bacteria, the last value being found in mesocosms with turbulence on Day 11.

Table 1. Number of bacteria attached to a TEP (n) as a function of its diameter (d , μm) at different sampling dates (except Day 9). Average values of the constants a and b come from the equation $n = ad^b$. All regression lines are highly significant ($p < 0.001$). N is the number of TEP analysed. From Days 0 to 7, data from enriched and non-enriched tanks were pooled as no significant differences were observed in the effects of nutrients between tanks (see Table 2). For Day 11, data (N) from non-enriched and enriched tanks were separated due to the significant interaction between nutrient addition and turbulence (ANCOVA: $F = 3.86$, $p = 0.02$). For details of experimental conditions see 'Materials and methods', 'Study site and sampling'

Fig. 2. Number of bacteria attached to a TEP as a function of its diameter (d , μm) at Day 1 and Day 11 in still (NT0, T0, ●) and turbulent mesocosms (T2, T4, NT2, NT4, ○). Regression lines were fitted to the observations. ESD: equivalent spherical diameter

The total numbers of attached bacteria in still and turbulent treatments were compared with the predicted abundances of attached bacteria estimated using encounter rate B (from Kiørboe et al. 2002), TEP and total bacterial concentrations. Results showed that the total number of bacteria attached to TEP (ml^{-1}) in still tanks represented $\sim 33\%$ (slope of bacterial concentration observed vs. predicted) of the calculated bacterial colonization, while attachment explained 40% of the predicted abundances of attached bacteria in turbulent tanks (Fig. 3).

Bacterial abundance, production and percentage of attached bacteria

At the start of the experiment, bacterial abundance in mesocosms ranged from 2×10^6 to 2.7×10^6 cells ml^{-1} . Then a moderate increase in abundances was observed in enriched turbulent tanks, reaching a maximum of 4.7×10^6 cells ml^{-1} on Day 3 at the higher tur-

bulence level (NT4, Fig. 4A). A comparison of total bacterial concentrations between treatments showed no significant effect of nutrient addition or turbulence (ANOVA; $F = 0.11$, $p = 0.89$, $N = 36$), although higher bacterial concentrations were observed in enriched turbulent tank NT2. However, the fraction of attached bacteria was higher in enriched turbulent tanks (Fig. 4B). TEP-attached bacteria ranged from 1.3 to 56.4% of the total numbers of bacteria. Low values occurred in non-enriched tanks, with an increase in proportions on Day 11 in turbulent tanks (12 and 15% in T2 and T4, respectively). In nutrient-enriched tanks, the proportion of attached bacteria increased from Day 3 to reach peak concentrations in turbulent tanks NT2 and NT4 (36.4 and 56.4%, respectively).

Table 2. Two-way ANCOVA of bacterial colonization of TEP at different sampling dates (except Day 9), with nutrients and turbulence as factors. N: number of samples, ns: non significant ($p > 0.05$)

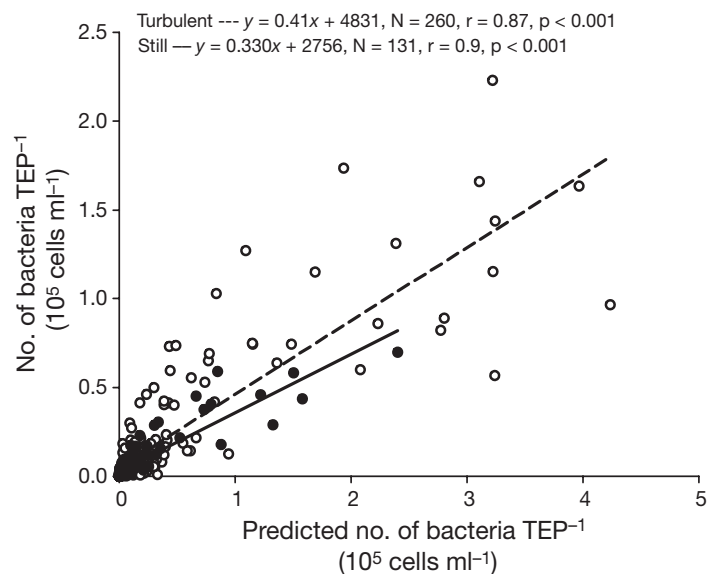

Fig. 3. Comparison between bacteria attached to TEP (cells ml^{-1}) and predicted number of bacteria attached to TEP (based on encounter rate B , abundance and size of TEP and bacterial concentrations). Calculations were done for total numbers of bacteria attached to each size class of TEP for each treatment and sampling day in still (●) and turbulent (○) mesocosms ($N = 383$)

Fig. 4. (A) Total bacterial abundances (10^6 cells ml^{-1}) and (B) percentage of bacteria attached to TEP in still (T0, NT0) and turbulent (T2, T4, NT2, NT4) mesocosms. Error bars: SDs from replicate samples

Fig. 5. Correlations between bacterial production ($\mu\text{mol C l}^{-1} \text{d}^{-1}$) and carbon content of TEP (TEP-C, $\mu\text{g C ml}^{-1}$) in enriched turbulent (O, NT2, NT4; $n = 32$; $p < 0.001$) and enriched still (●, NT0; $n = 16$; ns) mesocosms. Regression lines were fitted to the data

The bacterial production (BP) at the beginning of the experiment was on average $3.17 \pm 0.47 \mu\text{mol C l}^{-1} \text{d}^{-1}$. In non-enriched tanks, BP remained low and decreased on Day 11 to 0.42, 0.60 and $0.93 \mu\text{mol C l}^{-1} \text{d}^{-1}$ in T0, T2 and T4, respectively. In nutrient-enriched mesocosms, higher production rates were observed with turbulence, with maximum BP ($11.21 \mu\text{mol C l}^{-1} \text{d}^{-1}$) on Day 9 in the NT2 tank. In all mesocosms, total

bacterial abundance was neither correlated to TEP concentration nor to TEP-C content (Pearson's $r = 0.253$ and 0.210 , respectively; $p > 0.05$). Conversely, the normalized concentrations of attached bacteria were tightly coupled to TEP concentration and TEP-C content (Pearson's $r = 0.88$ and 0.89 , respectively; $p < 0.0001$). The bacterial production rates in enriched turbulent mesocosms were positively correlated to TEP concentration (Pearson's $r = 0.67$, $p < 0.001$) and to TEP-C; however, no correlation was found in enriched still tanks (Fig. 5). In non-enriched tanks, there were no significant correlations of bacterial production with TEP concentration and TEP-C content (Pearson's $r = 0.04$ and 0.07 , respectively).

Community composition of bacteria and TEP

Between the 2 domain probes used in this experiment, the EUB338 probe showed a high percentage of positive cells, with the proportion of Eubacteria detected varying from 55.7 to 88.7% of DAPI counts (median: 72.5; CV: 1.6 to 24.7). The high percentage

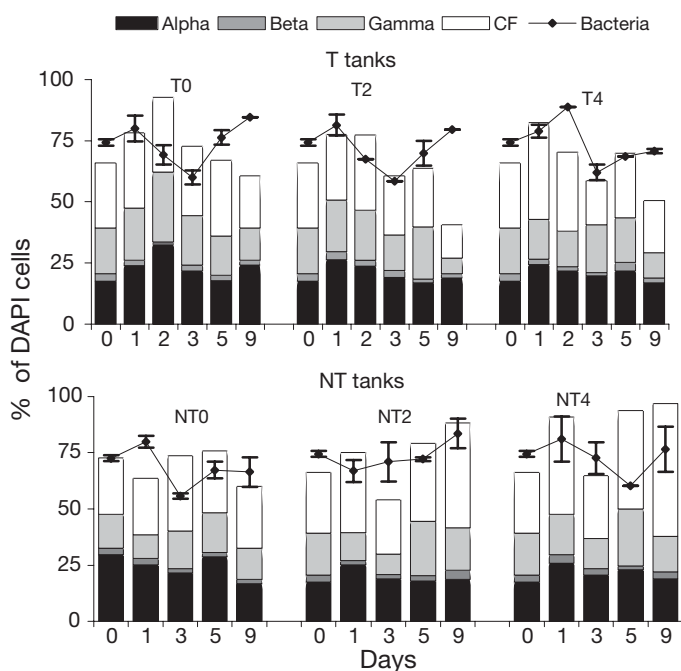

Fig. 6. Community structure of the bacterioplankton as determined by *in situ* hybridization with rRNA-targeted fluorescent oligonucleotide probes in different mesocosms. Probe data are given as % of DAPI cells. Specifications of the probes are as follows: EUB338 for Bacteria, ALF968, BET42a and GAM42a for Alpha, Beta and Gamma-subclass Proteobacteria, respectively, and CF319 for the *Cytophaga-flavobacterium* cluster. Data from Day 2 are missing in nutrient-enriched tanks

of positive cells indicated high activity and growth of bacteria. In general, the proportion of Eubacteria decreased at Days 3 to 5 and increased again until the end of the experiment (Fig. 6). There were no significant differences in the relative abundance of Eubacteria between treatments (ANOVA; $F = 0.57$, $p = 0.54$, $N = 66$). The proportion of cells detected with the Archaea probe was below the detection limit. The fraction of microorganisms hybridizing with the *Alphaproteobacteria* probe increased from 16 to 33.5% of DAPI counts (median: 20.4), while those hybridizing with the *Betaproteobacteria* and *Gamma-proteobacteria* probes varied from 1.3 to 5% (median: 3.1) and 6 to 28.7% (median: 17.8), respectively. Members of the *Cytophaga-Flavobacterium* cluster are the most abundant and accounted for 13.7 to 59% of total cells in the mesocosms (median: 27.3; CV: 1.6 to 24.7). Due to the rather good detection efficiency of Eubacteria, the sum of the fractions of the Alpha, Beta, Gamma-subclass and *Cytophaga-Flavobacterium* cluster detected by the various probes used ranged from 33 to 75% of the cells detected by EUB338. Results showed few effects of turbulence and nutrient availability on the proportion of different proteobacteria subclasses with time. The most important changes occurred in the *Cytophaga-Flavobacterium* cluster. In still tanks, the proportion of cells detected with the CF319 probe was nearly constant throughout the experiment. However, in turbulent tanks, the dynamics were complex. While the proportion of cells detected decreased from Day 3 to the end of the experiment in non-enriched tanks, it increased to reach 46 and 59% of total cells at Day 9 in mesocosms receiving inorganic nutrients and turbulence together (NT2 and NT4 tanks, respectively; Fig. 7). The increase in the proportion of the *Cytophaga-Flavobacterium* cluster corresponded with the diatom bloom and subsequent TEP formation (Fig. 1A,B). The analysis of the composition of particle-associated bac-

teria (using filters stained with Alcian blue and FISH) showed that the *Cytophaga-Flavobacterium* population increased with bloom senescence on Day 9, with this population comprising 85 and 90% of the total attached bacteria at intermediate and high levels of turbulence, respectively. In mesocosms without turbulence, attached bacteria were characterized by a mixture of populations mainly composed of the *Cytophaga-Flavobacterium* cluster and *Alphaproteobacteria* (33 and 28% of the total DAPI-stained cells, respectively).

DISCUSSION

TEP–heterotrophic bacteria interactions

Bacteria colonized most of the TEP present in the mesocosms, with significant differences in colonization between treatments. TEP may act as efficient scavengers for many substances such as amino acids (Schuster et al. 1998). TEP is also a direct site for sorption of nutrients and trace metals, such as manganese and iron (Beauvais 2003), thereby providing a substrate for bacterial growth (Kirchman et al. 2003). The effects of nutrient addition and turbulence on TEP dynamics as studied by Beauvais et al. (2006) in the same mesocosms showed that TEP production is more a function of higher phytoplankton concentrations achieved in nutrient-enriched treatments.

The effect of turbulence was likely indirect, i.e. through an increase in the growth rates of diatoms that actively exude TEP precursors, particularly when nutrients become exhausted. Variations in microbial colonization of TEP have been explained by variability in the composition of TEP precursors, in degradability of TEP (Kepkay & Johnson 1988, Passow & Alldredge 1994) and in grazing pressure (Mari et al. 2004). In the present experiment, the increase in the rate of bacterial

Fig. 7. Percentages of *Cytophaga-flavobacterium* clusters in the different mesocosms. Data are given as % of DAPI cells

colonization of TEP appeared linked to the rapid formation of TEP after the diatom bloom in enriched turbulent tanks. Freshly produced TEP are probably more reactive and readily colonizing them could be more beneficial for bacteria. Colonization patterns in the present study suggest that interactions between TEP and bacteria may be more complex. The addition of nutrients and turbulence in mesocosms did not significantly support higher bacterial abundance and no correlation was found between bacterial concentrations and TEP. However, the higher colonization rates

in nutrient-enriched turbulent mesocosms (up to 56.4%) was accompanied by higher bacterial production rates and was positively correlated to TEP. These correlations highlight the finding that the higher bacterial productivity was due to a larger fraction of attached bacteria.

It has been shown in freshwater environments that particle-associated bacteria can account for a large proportion of the total bacterial production (Simon et al. 2002). While total bacterial numbers remained more or less constant in our experiment and did not reflect any changes in bacterial activities, changes in bacterial production occurred with simultaneous changes in the community structure (i.e. the percentages of the *Cytophaga-Flavobacterium* cluster increased significantly, this group being the dominant bacteria attached to TEP). Among the marine heterotrophic bacterioplankton, members of the *Cytophaga-Flavobacteria-Bacteroides* (CFB) phylum are known to be common as attached bacteria (DeLong et al. 1993, Riemann et al. 2000). *Cytophaga-Flavobacteria* also represented a significant part of surface-attached and free-living microbial assemblages in nutrient-rich micro-environments associated with phytoplankton blooms (Fandino et al. 2005). The dominance of surface-attached bacteria on marine snow or detritus could be explained by the presence of specific profiles of hydrolytic enzymes adapted to degrade biopolymers including complex polysaccharides, indicating their major role in the marine carbon cycle (Bauer et al. 2006). Lemarchand et al. (2006) have shown that the *Cytophaga-Flavobacterium* group and Betaproteobacteria have higher enzymatic activities than free-living bacteria and are the dominant groups attached to particles in lakes. They also found positive relationships between TEP and glycolytic activities.

Comparison of Proteobacteria in our mesocosms revealed minor variation in the relative abundance of the different subclasses with time and with treatments. Moreover, we detected a decrease in the proportion of the *Cytophaga-Flavobacterium* population in non-enriched turbulent tanks. The decrease could have been due to less carbon excreted by phytoplankton in the relatively nutrient-poor mesocosms, which perhaps favored the appearance of other phylogenetic groups adapted for growth in low substrate concentrations, most notably Planctomycetales that is widespread in marine ecosystems and may have been missed by our EUB338 probe (Gade et al. 2004). However, we cannot exclude confinement effects or other factors such as viral and/or grazing controls, which were not considered in the present study, but may also influence the abundance and diversity of the bacterial communities (Simek et al. 1997).

Turbulence effect on attached bacteria

In the present experiments, the abundance of attached bacteria increased significantly with TEP size in all treatments. Other authors have also reported this relationship for exopolymeric particles as well as for other marine aggregates (Mari & Kiørboe 1996, Ploug et al. 1999, Simon et al. 2002). The exponent (~1.5) of this relationship found by Mari & Kiørboe (1996) has been attributed to the fact that TEP have a fractal dimension. Consequently, the number of attached bacteria is directly proportional to TEP porosity. The present results showed that the slope values for the number of bacteria scaled with TEP size had large differences, varying from 1.15 on Day 1 in still tanks to 2.04 on Day 11 in turbulent tanks. Comparison between these slopes indicated that, for a given TEP diameter, bacterial colonization was greater in mesocosms under turbulence. This can be explained by the fact that bacteria are not inert particles and colonization is not only influenced by TEP size and concentration, but also by specific bacterial responses to their chemical and physical environment (Grossart & Ploug 2001, Grossart et al. 2007). According to Karp-Boss et al. (1996), free bacteria with cells smaller than the Kolmogorov and Batchelor length scale should not benefit from a flux of nutrients owing to turbulent advection as their inorganic nutrient uptake is dominated primarily by molecular diffusion. However, turbulence may enhance the flux of high molecular weight substrates such as serum albumin (BSA) and the polysaccharide dextran towards cells (Confer & Logan 1991). These indicate that at higher shear rates, fluid motion will decrease the diffusive sublayer thickness of bacteria, thereby increasing the nutrient uptake rate. Peters et al. (1998) observed higher bacterial abundance and activity under turbulence in a microbial community. These changes were accompanied by a higher nutrient recycling and an increase in dissolved organic matter flux to bacteria. In contrast, Moeseneder & Herndl (1995) observed lower bacterial production under turbulent conditions in the laboratory when phytoplankton and particles were present, although the turbulence rates used were higher than naturally occurring levels. Attached bacteria in our experiment could benefit from the effective increase in nutrient flux to the particle owing to turbulent advection by increasing their growth rates when nutrients are not saturated.

Kiørboe & Jackson (2001) suggested that bacteria could actively colonize aggregates. Comparing total bacteria attached to TEP in our experiment with predicted attachment rates within 1 h showed that ~37% of bacteria encountering a TEP colonized these particles, with colonization rates being higher (44%) in tur-

bulent tanks. The present results are crude estimations, but are consistent with those derived by Kiørboe et al. (2002), who on average estimated that 50 and 92% of the bacteria will encounter an aggregate within 7 h and in 1 d, respectively. As the experiment was conducted on a time scale of days, we observed some time-dependent differences, from little colonization at the beginning of the study to increased colonization at the end. Not all bacteria encountering a particle will necessarily attach; the encounter rate depends on the size distribution and concentration of particles and on the concentration and motility of bacteria (Kiørboe et al. 2002). However, even with the variability in encounter rates, the higher coefficients in turbulent tanks suggest that the shear present under turbulence would enhance the encounter probability. Even if stickiness was not measured in this experiment, we assumed a high stickiness coefficient of TEP (Passow et al. 1994, Logan et al. 1995) after a diatom bloom, which might enhance coagulation efficiency that could facilitate bacterial attachment. Thus, turbulence may affect bacteria-TEP interactions indirectly through its effects on the availability of different substrates, as well as directly by increasing encounter rates. Consequently, attachment to particles such as TEP can result in significant advantages for bacteria. Fluid advection through porous aggregates is higher than through dispersed particles (Logan & Hunt 1987).

The present results show that the rapid TEP formation triggered by the release of large quantities of dissolved organic carbon after the phytoplankton bloom likely stimulated the activity and growth of attached bacteria. It appears that the added nutrients and subsequent TEP production can be used by bacteria more efficiently under turbulent conditions through a shift in group-specific composition towards more attached bacteria with higher production rates.

This study also shows the highly dynamic nature of TEP and emphasizes its role as organic substrates for bacteria. TEP could greatly influence the composition and activity of particle-associated bacteria. Turbulence may produce synergistic effects changing the availability of different organic matter fractions to bacteria and favoring attachment rates.
