Abstract. The distributions of the bio-essential trace element dissolved cobalt (*DCo*) and the apparent particulate Co (*PCo*) are presented along the GEOTRACES-A02 deep section from 64° N to 50° S in the western Atlantic Ocean (longest section of international GEOTRACES marine environment program). *PCo* was determined as the difference between total cobalt (*TCo*, unfiltered samples) and *DCo*. *DCo* concentrations ranged from 14.7 pM to 94.3 pM, and *PCo* concentrations from undetectable values to 18.8 pM. The lowest *DCo* concentrations were observed in the subtropical domains, and the highest in the low-oxygenated Atlantic Central Waters (ACW), which appears to be the major reservoir of *DCo* in the western Atlantic. In the Antarctic Bottom Waters, the enrichment in *DCo* with aging of the water mass can be related to suspension and redissolution of bottom sediments as well as diffusion of *DCo* from abyssal sediments. Mixing and dilution of deep water masses, rather than scavenging of *DCo* onto settling particles, generated the meridional decrease of *DCo* along the southward large-scale circulation in the deep western Atlantic. Furthermore, the apparent scavenged profile of *DCo* observed in the deep waters likely resulted from the persistence of relatively high concentrations in intermediate waters and low *DCo* concentrations in underlying bottom waters. We suggest that the 2010 Icelandic volcanic eruption could have been a source of *DCo* that could have been transported into the core of the North-east Atlantic Deep Waters. At intermediate depths, the high

concentrations of *DCo* recorded in the ACW linearly correlated with the apparent utilization of oxygen (AOU), indicating that remineralization of *DCo* could be significant (representing up to 37 % of the *DCo* present). Furthermore, the preferential remineralization of phosphate (P) compared to Co in these low-oxygenated waters suggests a decoupling between the deep cycles of P and Co. The vertical diffusion of *DCo* from the ACW appears to be a significant source of *DCo* into the surface waters of the equatorial domain. Summarizing, the dilution due to mixing processes rather than scavenging of *DCo* and the above-mentioned remineralization could be the two major pathways controlling the cycling of *DCo* into the intermediate and deep western Atlantic.

1 Introduction

In the context of the international GEOTRACES program, unprecedented efforts are underway to map the distribution of trace elements and isotopes in the global oceans. Cobalt (Co) is among the important micronutrients highlighted in this program. Dissolved cobalt (*DCo*) typically occurs at concentrations lower than 150 pM in the open ocean (Knauer et al., 1982; Martin et al., 1990; Fitzwater et al., 2000; Saito and Moffett, 2001; Saito et al., 2004; Ellwood, 2008; Noble et al., 2008; Pohl et al., 2011; Bown et al., 2011), requiring sensitive analytical techniques for its detection (Vega and van den

Berg, 1997; Cannizzaro et al., 2000; Saito and Moffett, 2001; Milne et al., 2010; Shelley et al., 2010). Previous studies have suggested that *DCo* could be an hybrid-type metal (Bruland and Lohan, 2003; Noble et al., 2008), with a nutrient-like distribution in surface waters (Martin et al., 1993; Saito and Moffett, 2002; Saito et al., 2004; Jakuba et al., 2008; Noble et al., 2008; Saito and Goepfert, 2008; Bown et al., 2011) and a scavenged-type distribution in the deep ocean (Knauer et al., 1982; Wong et al., 1995; Noble et al., 2008; Boyd and Elwood, 2010). Biological uptake by cyanobacteria (Saito et al., 2002), recycling, organic complexation, scavenging and regeneration processes are suspected to strongly impact the distribution of *DCo* in the surface ocean (Saito and Moffett, 2001, 2002; Noble et al., 2008, 2012; Bown et al., 2011, 2012a). In addition, other important sources of *DCo* to surface waters, such as river (Tovar-Sanchez et al., 2011) or atmospheric deposition (Shelley et al., 2012), may significantly impact its surface distribution.

In the water column, cobalt and manganese (Mn) often cycle together through a removal pathway of co-oxidation with manganese driven by microbes, but the biological assimilation of *DCo* can uncouple the Mn–Co relationship in surface waters (Moffett and Ho, 1996). Furthermore, previous studies showed high *DCo* concentrations in oxygen-depleted waters (Saito et al., 2004; Pohl et al., 2011; Noble et al., 2012) that can be partly related to slowed microbial oxidation of *DCo* decreasing its scavenging rate (Noble et al., 2012). On the other hand, the low solubility of inorganic Co in oxygenated waters and the affinity of *DCo* for particles have been invoked to explain why *DCo* does not seem to accumulate in the deep waters along the thermohaline circulation (Bruland and Lohan, 2003) and to interpret the apparent scavenged-type profile of *DCo* observed in the deep ocean (Aparicio-Gonzalez et al., 2012). In fact, the scavenging of *DCo* onto settling particles and its stabilization in solution by the complexation with organic binding ligands could be the two major pathways controlling the internal cycling of *DCo* in the deep ocean (Saito and Moffett, 2001, 2002). Those pathways might drive the residence time of *DCo* in the deep waters, estimated 40–120 years, which is more than two orders of magnitude longer than in surface waters (e.g., 0.32 year; Saito and Moffett, 2002). Hydrothermal vents (Bruland and Lohan, 2003) and sediment resuspension (Bown et al., 2012a) can be the prevailing external sources of *DCo* to the bottom ocean. In addition, advection of water masses enriched in *DCo*, following contact with continental margins, can be a significant source of *DCo* and locally imprints the vertical *DCo* distribution in intermediate and deep waters (Wong et al., 1995; Saito et al., 2004; Noble et al., 2008; Bown et al., 2011, 2012b). Furthermore, large and mesoscale transport of *DCo*-enriched waters through the intermediate oceanic circulation has recently been evidenced in the poor-oxygenated Atlantic Central Waters (Noble et al., 2012) and Upper Circumpolar Deep Waters (Bown et al., 2011), as well as close to the Kerguelen Plateau (Bown et al.,

2012b). Nevertheless, despite these major findings our understanding of the biogeochemical cycle of cobalt in the ocean is still limited, notably in the western Atlantic Ocean where observations of the deep distribution of *DCo* are scarce.

In this study the vertical and meridional distributions of *DCo* and apparent particulate cobalt (*PCo*) are presented along the GEOTRACES-A02 section in the western Atlantic Ocean from the east coast of the Greenland Plateau (64° N) to the Malvinas Plateau (50° S). The GEOTRACES-A02 transect is revisiting the Atlantic GEOSECS (Geochemical Ocean Sections) program's section of 1972, crossing distinct biogeochemical areas such as subtropical, equatorial or sub-polar domains where different trophic chains are growing in each. Moreover, this section also encounters several water masses involved in the thermohaline circulation and surface jets, such as the North Atlantic Drift, known for its important role in climate regulation. The spatial distributions of *DCo* and its transportation across the entire deep western Atlantic Ocean are examined. Intercomparison between this data set and others, at three crossover stations located in different biogeochemical domains, are presented. The advection of *DCo* in the different intermediate and deep water masses flowing in the western Atlantic are studied to further understand its spatial distributions. In addition, the potential effect of the 2010 Icelandic volcano Eyjafjallajökull eruption on the distribution of *DCo* is investigated. We also investigate the role of the remineralization in the distribution of *DCo* at intermediate depths, and its relationship with phosphate. Finally, the roles of the dynamic structures and the vertical diffusion are considered as they may provide a link between the deep and surface distributions of *DCo*. However, the complete description of the cycling and budget of *DCo* in the surface waters along the GEOTRACES-A02 section will be discussed elsewhere (Dulaquais et al., 2014). This large and deep section together with the relatively high spatial resolution has given us the opportunity to present, for the first time, the largest comprehensive data set of cobalt in the western Atlantic Ocean.

2 Methods

2.1 Cruise track and sampling

The samples were collected from stations (St.) along the GEOTRACES-A02 section in the western Atlantic Ocean, the longest section of the international GEOTRACES program. Four expeditions conducted between 2010 and 2012 were necessary to complete this section spreading from 64° N to 50° S along the western Atlantic Ocean (Fig. 1). Three cruises were operated aboard the Dutch R/V *Pelagia* (legs 1, 2, 4) and one cruise aboard the British RRS *James Cook* (leg 3). The first cruise started in April 2010 from 64° N to Bermuda in the Sargasso Sea (St. 1–19), followed by the second leg from the station BATS to the Equator (St. 21–41).

Fig. 1. GEOTRACES-A02 cruises track along the western Atlantic Ocean. Sampling locations of the four legs are shown (leg 1 in red line from station 2 to station 19, leg 2 in green line from station 21 to station 41, leg 3 in blue line from station 1b to 18b and leg 4 in purple line from station 3c to 7c).

The section in the southwestern Atlantic (leg 3) from 50° S to the Equator was achieved in March 2011 (St. 1b–18b). An additional cruise (leg 4) was operated in August 2012 to complete the first leg that had been fragmented due to bad weather (St. 3c–7c).

A total of 47 stations with a vertical resolution of 12–16 depths between 9 m and 5930 m were sampled for dissolved cobalt analyses (DCo), and 15 stations for total (unfiltered) cobalt determinations (TCo). The apparent particulate cobalt concentrations (PCo) were calculated by subtraction of DCo from TCo . The complete data set of cobalt (dissolved, total, and apparent particulate) at all stations will be available at the international GEOTRACES data center (<http://www.bodc.ac.uk/geotraces/>).

Samples were taken using the TITAN-CTD frame of NIOZ (Netherlands), with 24 ultra-clean 24.4 L sampling bottles made of PVDF (polyvinylidene fluoride) plastic (de Baar et al., 2008). The frame was placed in a Class-100 container for sub-sampling (de Baar et al., 2008). Unfiltered samples were transferred into acid-cleaned 250 mL Nalgene™ LDPE (low-density polyethylene) bottles for

TCo analyses. The samples for DCo analyses were collected after filtration using 0.2 μm Sartobran™ 300 (Sartorius) cartridges under pure N_2 pressure (filtered 99.99 % N_2 , 0.7 atm) in acid-cleaned 250 mL or 500 mL Nalgene™ LDPE bottles. All samples were acidified at $\text{pH} \sim 2$ using ultrapure HCl ™ (Merck) immediately after their collection. Then the acidified samples were dark-stored in double bags at ambient temperature in preparation of their analyses in the shore-based laboratory.

2.2 Analytical method for cobalt analyses

2.2.1 Method

Prior to the analyses, the samples were UV-digested (Saito and Moffet, 2002; Shelley et al., 2010) for 3 h in acid-cleaned silica tubes using a 600 W high-pressure mercury vapor lamp (Bown et al., 2011), and left for an equilibration time of 48 h. Preliminary tests indicated that 3 h of UV-digestion were required to fully recover Co in surface and deep samples (data not shown).

Dissolved and total cobalt concentrations were determined by flow-injection analysis (FIA) and chemiluminescence detection following the method adapted from Shelley et al. (2010), as described in Bown et al. (2011). In this method, cobalt catalyzes the oxidation reaction of pyrogallol with hydrogen peroxide in an alkaline solution in the presence of cetyltrimethylammonium bromide (CTAB) and methanol. A chemiluminescent emission in the visible wavelengths proportional to the cobalt concentration is produced during this reaction. The system consists of one 10-port injection valve (VICI valves from VALCO instruments), which operates as an autosampler, and of two micro-electronically actuated injection valves (VICI valves from VALCO instruments) that use Tygon® tubes to inject the sample and the reagents. The flow injection is provided by a peristaltic pump (205 CA, Watson Marlow).

The reagents were prepared with trace metals quality reagents, as described in Bown et al. (2011). All reagents were prepared under a laminar flow hood (ADS Laminaire, ISO 5 class) in 1 L LDPE Nalgene® bottles with ultrapure water (MiliQ, 18.2 $M\Omega$) the day before the analysis and kept at room temperature for an overnight equilibration.

The sample was buffered online with ammonium acetate (0.3 M, ACS Reagents) and loaded onto an IDA-Toyoperal chelating resin to preconcentrate the cobalt contained in the sample. Then a HCl solution (0.1 M, Suprapur® Merck) was injected through the column to elute Co. The eluent was warmed in a 60 °C thermostatic bath to limit the interferences in the detection system due to bubbles (Shelley et al., 2010). The detection system consisted of a photomultiplier detector (Hamamatsu, H9319 series). The injection valves and the photomultiplier detector were operated on a laptop by a modified Labview® 8.4 interface (E. Duvieilbourg and M. Boye,

LEMAR). The electrical devices were connected to a modulator of current (ELLIPSEMAX 600, MGE/UPS Systems).

The Co concentrations were calibrated against two calibration curves made with standard additions of cobalt of 0, 12.5, 25, 50, 75 and 100 pM to seawater, and performed before and after each series of 8 or 12 samples. TCo and DCo concentrations were based on triplicate analyses of each sample using the mean peak height of the chemiluminescent signal, and corrected with respect to blank analyses. Two to four reagent blanks, including the buffer blank, were analyzed per series of 8–12 samples at the beginning and at the end of the series in acidified MilliQ water instead of the sample (Bowie and Lohan, 2009; Bown et al., 2011).

The final standard deviation of the measurement was calculated by an error propagation using the error on blanks, the calibration curves and the deviation of the triplicate analyses. The paired two-tailed t test shows that the differences between TCo and DCo (e.g., equivalent to apparent particulate Co) are statistically significant at the 95 % confident interval ($P < 0.05$, $t_{critical} = 2.84$, $t_{experimental} = 12.83$, $n = 203$), allowing reliable estimation of PCo concentration. The standard error on PCo was calculated by combining uncertainties of DCo and TCo measurements (e.g., $SD_{PCo} = (SD_{DCo}^2 + SD_{TCo}^2)^{0.5}$).

2.2.2 Analytical performance

The mean reagent blank (based on all blank determinations) was 4.2 ± 2.1 pM ($n = 180$) of Co in MilliQ ($n = 180$). The limit of detection of the method estimated as three times the standard deviation of the mean reagent blank was 6.3 pM ($n = 180$). Each series of samples was calibrated by running one or two samples collected during the “Sampling and Analysis of iron” (SAFe) program or GEOTRACES program. SAFe and GEOTRACES samples were UV-digested for 3 h prior to analysis and the results of DCo concentrations are reported in Table 1. The DCo concentrations we measured in the SAFe and GEOTRACES reference-samples are in excellent agreement with the consensus values (<http://www.geotraces.org/science/intercalibration/322-standards-and-reference-materials>). The DCo value obtained in the S-SAFe sample also falls in the consensus value despite the concentration being lower than the detection limit. The analytical precision of the method was determined from repeated analyses of the surface S-GEOTRACES reference sample, yielding an uncertainty of ± 3.8 % expressed as relative standard deviation on the mean ($n = 15$).

2.3 Hydrography

Hydrological parameters (S , T° , O_2 , conductivity, fluorescence and turbidity) were measured using an SBE9+ underwater sensor, an SBE3+ thermometer (± 0.001 °C), an SBE4 conductivity sensor (± 0.3 mS s⁻¹), an SBE43 dissolved oxygen sensor (± 2 %), a Chelsea Aquatracka MKIII

Table 1. Comparison of dissolved cobalt analyses obtained in the UV-oxidized samples by the FIA-chemiluminescence method used in the present study with consensus values reported by the Sampling and Analysis of iron (SAFe) and GEOTRACES programs. Water samples provided by SAFe and GEOTRACES from surface waters (SAFe S and GEOTRACES S) and deep waters (SAFe D1 and D2, and GEOTRACES D) were analyzed. Errors are given as standard deviation from average values.

Sample	DCo measured (pM)	Consensus value (pM)
SAFe S	5.1 ± 2.2 ($n = 25$)	4.8 ± 1.20
SAFe D1	42.3 ± 1.4 ($n = 15$)	45.4 ± 4.7
SAFe D2	44.2 ± 1.7 ($n = 25$)	45.7 ± 2.9
GEOTRACES S	29.8 ± 2 ($n = 35$)	31.8 ± 1.1
GEOTRACES D	63.2 ± 2.3 ($n = 25$)	65.2 ± 1.2

fluorometer (± 0.2 $\mu\text{g l}^{-1}$), and a Wetlabs C-Star transmissometer (± 0.02 % °C⁻¹; 25 cm, deep, red).

2.4 Macronutrients analysis

Nutrient samples were collected in 125 mL polypropylene bottles using a CTD-rosette (Seabird[®]) equipped with Niskin bottles. The analyses were performed on board from surface to deep waters samples. All the nutrients were analyzed by colorimetric methods, following the methods of Murphy and Riley (1962) for phosphate (HPO_4^{2-}), of Strickland and Parsons (1968) for silicate ($\text{Si}(\text{OH})_4^-$), and of Grasshoff et al. (1983) for nitrate (NO_3^-) and nitrite (NO_2^-).

3 Results

3.1 Circulation and dynamic structures

In the North Atlantic, the section crosses the subarctic gyre (SAG) between 64° N and 50° N, where the Labrador Sea Water (LSW) dives to form with the Arctic Bottom Water, the Western North Atlantic Deep Water (WNADW). Deeper, the Eastern North Atlantic Deep Water (ENADW) is also isolated in the SAG and forms, further south, with the WNADW the North Atlantic Deep Water (NADW) (Fig. 2). The well-oxygenated and dense waters of the subarctic gyre are separated, in the south, from relatively low-oxygenated, saline and warm waters of the North Atlantic subtropical gyre (NASG) by the North Atlantic subtropical front (NSTF) at $\sim 45^\circ$ N. The NSTF is characterized by a high anomaly of temperature ($+5$ °C) and by a strong eastward geostrophic current in surface waters (data not shown) which is likely to be the North Atlantic Drift (Reid, 1994).

In the NASG, low-density waters occur in the top 600 m due to relatively high salinity and temperature ($T^\circ > 10$ °C; $S > 35$) (Fig. 2). However, at 15° N and, to a lesser extent, at 4° N these saline waters are covered by relatively fresh

Fig. 2. Interpolated vertical sections of (a) temperature (T), (b) salinity (S) and (c) dissolved oxygen (O_2) along the GEOTRACES-A02 section in the western Atlantic, based on CTD data. The different water masses – LSW, NEADW, NADW, ACW, AABW, D-AAIW and UCDW – are identified by their physical features and are indicated in the figure panels. Stations sampled during leg 4 are labeled in red.

waters (Fig. 2) originating from the Amazon plume. The waters influenced by the Amazon plume are characterized by a relatively high Si : N ratio and turbidity (data not shown).

Leaving the NASG southwards, the section enters into the equatorial area (EA). Here, the zonal geostrophic velocities indicate the presence of several jets near the surface, such as the North Equatorial Current (NEC, at $5\text{--}10^\circ\text{N}$), the North Equatorial Countercurrent (NECC, at $\sim 3^\circ\text{N}$), the South Equatorial Current (SEC, at $5\text{--}10^\circ\text{S}$) and the South Equatorial Undercurrent (SEUC, at $\sim 5^\circ\text{S}$, 200 m depth), as described by Peterson and Stramma (1991). The equatorial domain is bordered by the NEC in the north and by the SEC in the south, both of which are characterized by westward surface geostrophic propagating vectors of correlating speeds (respectively 0.2 and 0.15 m s^{-1}). Below 100 m, the salinities and temperatures are lower than in the NASG, revealing denser waters. An oxygen minimum zone (OMZ; $O_2 < 150\text{ }\mu\text{M}$) was also observed under these surface currents, between 150 and 600 m (Fig. 2c). Part of this low O_2 signature was due to the advection of the poor-oxygenated

Atlantic Central Waters ($O_2 < 50\text{ }\mu\text{M}$; Noble et al., 2012), flowing westward from the African border across the Atlantic basin.

Southward, the section enters into the South Atlantic subtropical gyre (SASG) characterized, like in the North Atlantic, by low-density waters associated with relatively high salinities and temperatures (Fig. 2a and b). Despite strong eddy activity in this area, clearly observed in the geostrophic current field, the Malvinas–Brazil confluence (MBC), an eastward jet resulting from the Brazil current flowing southward and the Malvinas current flowing northward, can be located in the Argentine basin around 40°S (e.g., at station 6b; data not shown). The MBC separates the SASG with saline and relative oxygen-poor waters from the subantarctic waters (SAW).

Several water masses involved in the large-scale ocean circulation were characterized by depth (Fig. 2). For instance, the LSW was characterized by $34.9 < S < 34.8$ and $O_2 > 275\text{ }\mu\text{mol kg}^{-1}$ in the subarctic gyre at 60°N (Fig. 2). The ENADW ($S > 34.925$) circulates underneath the LSW, following the topography below 2500 m in the northern side of the section. The core of the ENADW is situated between 62°N and 45°N . The WNADW and the ENADW both form the NADW, spreading southward into the deep ocean from 60°N to 37°S (Tomczak and Godfrey, 2003). The Antarctic Bottom Water (AABW), characterized by $S < 34.8$ and $T^\circ < 1^\circ\text{C}$, is formed in the Weddell Sea (Reid, 1989; Gladyshev et al., 2008) and spreads at the bottom of the ocean below 4000 m. The AABW enters the Atlantic Ocean by the south and follows the topography until 3°N . To the north the bottom waters are a mix between AABW, Arctic Bottom Waters (ABW) and NADW (Tomczak and Godfrey, 2003). In the Southern Hemisphere, the relatively fresh Antarctic Intermediate Waters entering from the Drake Passage (D-AAIW; $S > 34.2$) are identified at intermediate depths between 500 and 1000 m. Finally, the oxygen distribution enables us to distinguish the different components of the Circumpolar Deep Waters (CDW; Whitworth and Nowlin, 1987), with its upper component (UCDW) at about 1500 m, marked by $O_2 < 190\text{ }\mu\text{mol kg}^{-1}$, and its intermediate component (ICDW) at about 2500 m with $O_2 > 210\text{ }\mu\text{mol kg}^{-1}$ (Fig. 2c). The intermediate waters in the equatorial domain are formed by a mix of AAIW and UCDW that both flow northward and of the Atlantic Central Waters (ACW) originated from the east Atlantic basin (Poole and Tomczak, 1999). However, it has to be noted that the transitions between the different water masses vary with the latitude (Fig. 2).

3.2 The nutrients distribution along the GEOTRACES-A02 section

Different biogeochemical domains were characterized in surface waters along the GEOTRACES-A02 section (Fig. 3). The surface waters of the SASG were marked by relatively

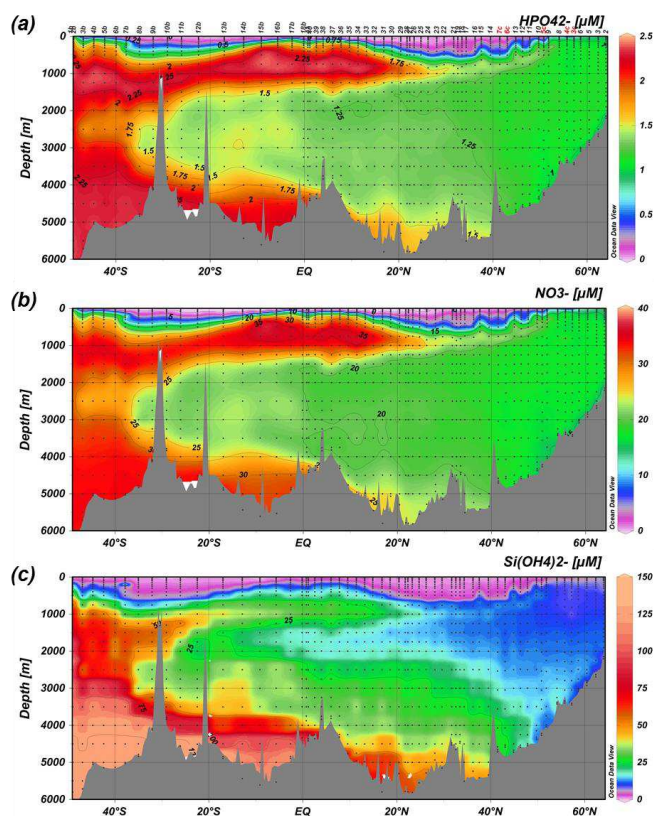

Fig. 3. Interpolated vertical sections of (a) phosphate, (b) nitrate and (c) silicate based on 1440 analysis of water-column samples collected and measured by NIOZ along the Netherlands area of GEOTRACES-A02 section. Stations sampled during leg 4 are labeled in red.

high phosphate and nitrate concentrations ($\text{NO}_3 > 10 \mu\text{M}$; $\text{PO}_4 > 0.8 \mu\text{M}$; Fig. 3). In the two subtropical domains, the extremely low nutrients concentrations (such as observed in the NASG where $\text{PO}_4 < 0.5 \mu\text{M}$, $\text{NO}_3 < 5 \mu\text{M}$, $\text{Si} < 5 \mu\text{M}$) were characteristic of oligotrophic conditions. However, a greater depletion of nitrogen relative to phosphate was observed in the upper 300 m of the SASG ($\text{N}:\text{P} < 10$) compared to the NASG ($\text{N}:\text{P} > 25$), probably due to a greater proportion of N_2 fixers, such as diazotrophic cyanobacteria, in the NASG than in the SASG (Mather et al., 2008). In the equatorial area, the intermediate waters were characterized by relatively high concentrations of nitrate and phosphate ($\text{NO}_3 > 34 \mu\text{M}$, $\text{PO}_4 > 2.3 \mu\text{M}$), whereas silicate concentrations were low ($5 \mu\text{M} < \text{Si} < 15 \mu\text{M}$), suggesting the incursion of D-AAIW formed in the southwestern Atlantic. South of the south subtropical front, the nutrients distribution showed, as for oxygen, the influence of the AAIW and UCDW with relatively high nutrients concentration in the top 200 m depths ($\text{NO}_3 > 20 \mu\text{M}$, $\text{PO}_4 > 1.2 \mu\text{M}$). In the deep ocean the nutrients distribution reflected a combination of aging and advection of water masses (Fig. 3). The spreading of young NADW can be followed with the low-nutrients

signature ($\text{Si} < 35 \mu\text{M}$; $\text{NO}_3 < 20 \mu\text{M}$; $\text{PO}_4 < 1.5 \mu\text{M}$). Phosphate and nitrate concentrations increased southward in the deep ocean (Fig. 3) due to mixing of Arctic waters (poor in nutrients) with nutrients-enriched Antarctic waters. The AABW was characterized by relatively high nutrients concentration ($\text{Si} > 130 \mu\text{M}$; $\text{NO}_3 > 30 \mu\text{M}$; $\text{PO}_4 > 2 \mu\text{M}$), which decreased northward. The nutrients concentration in the Circumpolar Deep Waters was similar to those of AABW, but the concentrations in the ICDW were a little bit lower than those in the UCDW. The silicate levels are depleted in the AAIW compared to other Antarctic waters.

3.3 The comprehensive distribution of cobalt in the western Atlantic

The meridional and vertical distributions of DCo along the GEOTRACES-A02 section are presented in Fig. 4a. Dissolved cobalt concentrations range from 14.72 ± 1.43 to $93.27 \pm 3.31 \text{ pM}$ along the section. The lowest concentration was observed in surface waters of the SASG (e.g., at 9 m depth at St. 11b – 26°S), whereas the highest were recorded in the OMZ of the equatorial area (e.g., at St. 15b – 9°S at 290 m depth). The vertical distributions of the apparent particulate cobalt concentrations (PCo) are presented in Fig. 4b. The apparent particulate cobalt concentrations ranged from near undetectable values (e.g., the difference between unfiltered and filtered samples analyses is nearly null) to $18.85 \pm 3.97 \text{ pM}$ (e.g., at St. 17 – 34.3°N at 5510 m depth). The PCo/DCo ratio ranged from 0.06 % (St. 17; 2500 m) to 44 % (St. 26, 25 m), with a mean of 7 % ($n = 192$).

Different vertical distributions of DCo were observed in each biogeochemical domain (Figs. 4 and 5). The distribution of DCo showed an apparent scavenged-like profile in the northern subarctic gyre (Figs. 4a–5a), with relatively higher concentrations in surface waters ($\text{DCo}_{\text{upper } 200 \text{ m}} > 70 \text{ pM}$) compared to deeper waters ($\text{DCo}_{\text{below } 2000 \text{ m}} < 60 \text{ pM}$). In this domain, lower surface DCo concentrations were recorded in 2012 during leg 4 (e.g., $42.1 \pm 2.15 \text{ pM}$ at St. 3c, and $44.23 \pm 1.26 \text{ pM}$ at St. 4c, at 25 m depth) compared to those observed in 2010 during leg 1 (e.g., mean $\text{DCo} = 64.56 \pm 5.25 \text{ pM}$ at 25 m ($n = 4$), with a DCo maximum of $68.2 \pm 1.08 \text{ pM}$ at St. 5). At intermediate depths (500–1000 m), the LSW was characterized by relatively high DCo concentrations ($\text{DCo} \sim 70 \text{ pM}$) compared to those found in the ENADW ($\text{DCo} \sim 55 \text{ pM}$ below 2000 m). In this domain, the apparent particulate cobalt distribution showed relative PCo maxima in the subsurface (ranging from 5.9 ± 1 to $10.4 \pm 1.96 \text{ pM}$), and decreasing concentrations with depth (until undetectable levels around 1500 m depth). Maxima of PCo ($> 10 \text{ pM}$) were then observed near the bottom (at St. 2 and 11).

In contrast, DCo was depleted in the surface waters of the two subtropical domains and increased with depth below the nutricline, featuring a nutrient-like distribution

Fig. 4. Interpolated vertical sections of (a) dissolved cobalt (DCo , pM) and (b) apparent particulate cobalt (PCo , pM) based on 675 analyses for DCo and 203 analyses for PCo along the GEOTRACES-A02 section in the western Atlantic. Stations sampled during leg 4 are labeled in red. The domains of SAG, NASG, EA, SASG and SAW are characterized by the macronutrients concentrations and by the surface currents (e.g., NAD, NEC, SEC, and MBA).

(Figs. 4a–5b). However, DCo are slightly lower and shallower in the SASG (mean DCo value of 23.01 ± 4.17 pM, $n = 9$) compared to those found in the NASG (mean DCo value of 28.8 ± 4.8 pM, $n = 15$). Subsurface relative maxima of DCo were observed at about 10 m depth at a few stations in the NASG. Deep relative DCo maxima were also observed at around 1250–1750 m depth in the NASG, which are in the core of NADW and below the oxygen minima. On the contrary, relative DCo maxima and oxygen minima were often located at the same depth in the SASG, within the core of the mixed NADW. In the AABW of the SASG, DCo was on average equal to 42.8 ± 2.23 pM ($n = 15$). In the two subtropical gyres, the PCo concentrations ranged from undetectable value (e.g., at 2500 m of St. 17) to 18.85 ± 3.97 pM (at 5510 m–34.3° N). Like in the northern latitudes, relatively high PCo concentrations were observed in the surface waters, decreasing with depth, and increasing again near the seafloor (Fig. 5e). The PCo distribution also showed, like DCo , relatively lower PCo concentrations in

the subsurface waters of the SASG (< 5 pM) compared to the NASG (> 5 pM).

In the equatorial area, the DCo distribution was characterized by low concentrations in the top 100 m (mean $DCo_{f100m} = 29.6 \pm 9$ pM, $n = 44$), a sharp increase between 100 and 250 m (mean $DCo_{f100-250m} = 61.7 \pm 13$ pM, $n = 10$), which continued to increase, reaching maximum values at about 400 m depth (mean $DCo_{f250-400m} = 73.2 \pm 10$ pM, $n = 19$) (Figs. 4–5c). These maximum concentrations were the highest values recorded along the section and reached values up to 93.27 ± 3.31 pM (at 9° S). Furthermore, these DCo maxima strongly correlated with the oxygen depletion ($\Delta DCo/\Delta O_2 = -0.28 \mu M M^{-1}$, $R^2 > 0.66$; $n = 57$; $P < 0.05$). Between 1000 and 2500 m depth, the DCo concentrations were in the same range as those observed at 100–250 m depths (mean $DCo_{f1000-2500m} = 67.6 \pm 5.8$ pM, $n = 33$). Deeper DCo concentrations decreased to a mean value of 41 ± 4 pM ($n = 15$) below 4000 m. The distribution of PCo in the equatorial domain

Fig. 5. Typical vertical distribution of dissolved (*DCo*) and apparent particulate (*PCo*) cobalt against depth in the different biogeochemical domains: in the SAG, *DCo* (a) and *PCo* (d) are shown for Station 2 (64° N, 34.25° W), St. 8 (54° N, 45.84° W), St. 5c (50° N, 44° W) and St. 11 (48° N, 39.4° W); in the north and south subtropical domains *DCo* (b) and *PCo* (e) are shown at St. 17 (34.3° N, 55.4° W), St. 26 (23° N, 65.55° W), St. 30 (18.5° N, 57.6° W), St. 12b (22.47° S, 32.7° W) and St. 8b (35° S, 39.4° W); and in the equatorial area *DCo* (c) and *PCo* (f) are presented at St. 36 (7.8° N, 48.9° W), St. 40 (1° N, 39.7° W) and St. 15b (9° S, 28° W).

was similar to that observed in the other domains, with several extremely low (undetectable) values in deep waters and relatively higher concentrations ($PCo > 5$ pM) in surface waters, up to a maximum value of 10.24 ± 2.1 pM observed at 10 m at St. 40 (1.15° N). A different pattern was, however, observed in the deep waters at 8° N (St. 36), where significant and increasing *PCo* concentrations were detected between 3500 m (1.52 ± 0.7 pM) and 4315 m (11.73 ± 1.9 pM), as well as at 3° S (St. 17b) where extremely high *PCo* concentrations were measured at 3500 m depth (12.53 ± 2.4 pM). In the surface waters, high *PCo* concentration (~ 10 pM) was detected at 1° N (St. 40) in the Amazon plume.

In the area of the Brazil–Malvinas confluence, *DCo* increased southward in the surface waters. The vertical distribution showed the highest *DCo* concentrations in the core of D-AAIW (100–600 m; Fig. 4a), whereas *DCo* levels decreased in deeper waters, generating an apparent scavenged-type distribution at latitudes of 49–49.5° S (St. 1b–2b). The *DCo* concentrations observed in the youngest AABW flowing in this area were the lowest values recorded in the core of the AABW along the section ($DCo_{f4000-6000\text{ m}} = 34.9 \pm 3$ pM). Only one profile of *PCo* has been obtained in this area at 49° S (St. 2b). It showed relatively high *PCo* concentrations in the upper 300 m ($PCo > 6$ pM), and, as for

the other domains, undetectable *PCo* concentrations in deep waters, except at 5000 m where *PCo* reached a maximum (11.8 ± 3.4 pM).

4 Discussion

4.1 Comparison of data sets of dissolved cobalt concentrations obtained at three crossover stations

Three crossover stations were occupied along the GEOTRACES-A02 section, at the Bermuda Atlantic Time Series BATS station (64.17° W, 31.7° N), at 9° S during the US CoFeMUG cruise in 2007, and at 40° S during the English GEOTRACES-A10 section in 2012 (Fig. 6).

Station BATS (St. 21) in the Sargasso Sea was occupied on 13 June 2010 during our GEOTRACES-A02 section sampling cruise. The *DCo* concentrations analyzed by the FIA-chemiluminescence method (this study, Fig. 6a and d: blue diamonds) are compared to those obtained by ICP-MS methods either in the same samples (Middag et al., 2014; Fig. 6a and d: yellow dots), or during other sampling cruises (Billier and Bruland, 2012: green triangles in Fig. 6a and d; Middag et al., 2014: red squares in Fig. 6a and d). All samples were

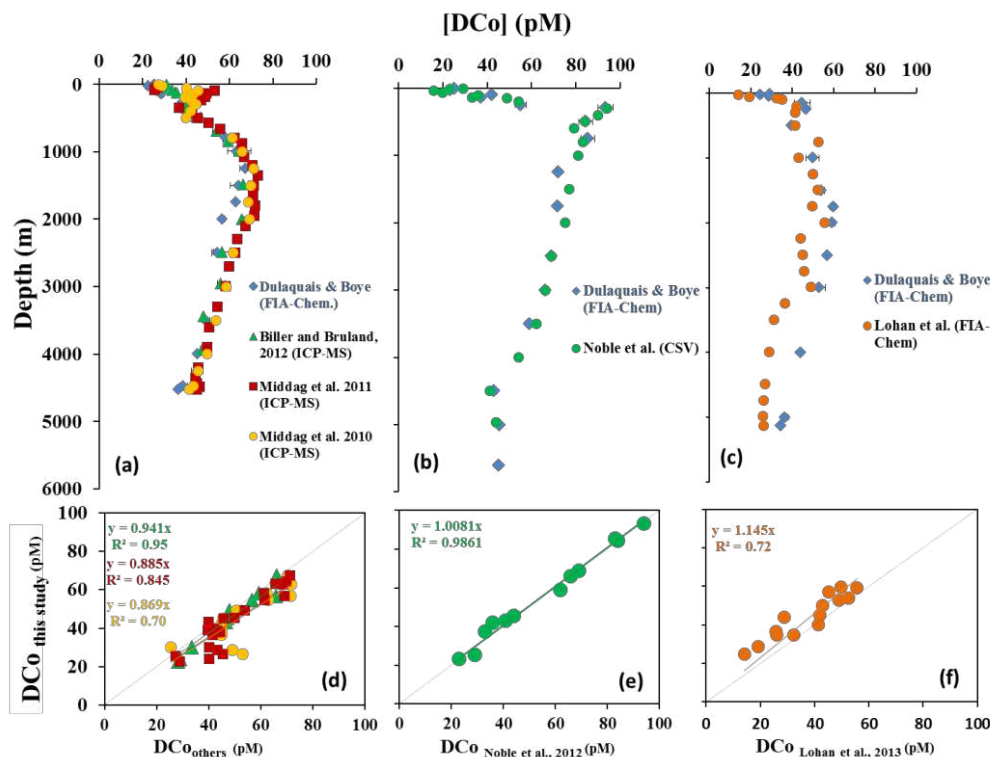

Fig. 6. Intercomparison of DCo data sets at the crossover station BATS (**a**, **d**) between this study (blue diamonds) and ICP-MS method by Biller and Bruland (2008) (green triangles) and by R. Middag et al. (personal communication, 2014) (yellow dots = samples from the 2010 Dutch GEOTRACES-A02 cruise; red squares = samples from the 2011 American GEOTRACES-A03 cruise); at the crossover station located at 9° S (**b**, **e**) between this study (blue diamonds) and the CSV method by Noble et al. (2012) (green dots); and at the crossover station at 40° S (**c**, **f**) between this study (blue diamonds) with FIA-chemiluminescence method by M. C. Lohan et al. (personal communication, 2014) (orange dots = samples from the 2010 English GEOTRACES-A10 cruise).

analyzed after UV treatment. In the deep waters, no significant differences were observed between the different data sets, even when samples were taken in different years. On the contrary, differences were observed in surface waters (25–200 m), with systematic higher DCo values using the ICP-MS compared to the FIA-chemiluminescence method. It is possible that seasonal variability, especially of the Co dust deposition – which widely varies in this area (Shelley et al., 2012), would cause those variations of DCo levels recorded in surface waters (Biller and Bruland, 2012; Middag et al., 2014; Fig. 6a and d: green triangles and red squares, respectively). However, further investigations are needed because differences are also observed in the same set of samples (this study; Middag et al., 2014: yellow dots in Fig. 6a and d), yielding an offset of 6–20 pM DCo in the top-100 m between the ICP-MS method and FIA-chemiluminescence analyses.

At 9° S, the DCo concentrations analyzed by FIA-chemiluminescence in the samples collected during the GEOTRACES-A02 section sampling cruise (23 March 2011, St. 15b, this study) were compared with data analyzed by cathodic stripping voltammetry after UV-treatment, but in non-acidified samples (Noble et al., 2012). Despite the fact that the two stations are not exactly at the same location and that

they were sampled in different years, the hydrography and the nutrient distributions were similar (data not shown), allowing the comparison of the DCo data sets. The comparison showed an excellent correlation ($R^2 > 0.98$; Fig. 6e), suggesting that both analytical methods were in good agreement. Less temporal variability in this area due to lesser dust inputs or coastal influences potentially allowed for the good agreement when comparing the two methods at this station.

At 40° S, the two DCo data sets sampled during the GEOTRACES-A02 section cruise (10 March 2011, St. 6b, this study) and the GEOTRACES-A10 section cruise (January 2012; Lohan et al., 2014) were obtained using similar FIA-chemiluminescence methods after UV-digestion of the acidified sample. This method showed an overall good agreement between the two data sets in the upper 3000 m (Fig. 6c and f), and an offset of 8–15 pM in the deepest waters below 3000 m (Fig. 6c). The analytical methods and sample treatments were similar. However, this station was located on the Malvinas–Brazil confluence. Its position and intensity widely vary with season and with the incursion of subantarctic waters, notably of the Antarctic Intermediate Waters and Circumpolar Deep Waters. The seasonal variations can explain the differences of DCo observed at intermediate and

deeper depths between the two data sets. In the deepest waters, the difference observed in the nepheloid layer can be due to differences in the resuspension/dissolution of benthic sediments. Further investigation is needed to determine the sources of these differences.

4.2 Large-scale transportation of dissolved cobalt in the western Atlantic

The behavior of *DCo* in the deep ocean is still poorly understood due to the lack of observations in the full water column, notably in the western Atlantic Ocean, as well as in the Indian and the central Pacific oceans. The few studies that report *DCo* concentrations in the deep ocean suggested a decrease of *DCo* levels in the deep waters from the Atlantic Ocean (80.8 pM), to the Southern Ocean (39.7 pM), and to the Pacific (28.8 pM) (Bown et al., 2011; Aparicio-Gonzalez et al., 2012). This observation has led to the hypothesis that there is no accumulation or conservation of *DCo* along the thermohaline circulation, and to classify *DCo*, in the literature, among either the scavenged-type element like aluminium (Aparicio-Gonzalez et al., 2012) or the hybrid-type metals, those elements that have a nutrient behavior in surface waters and are strongly influenced by scavenging processes in the deep waters (Noble et al., 2008). However the scavenging of *DCo* invoked to interpret the deep inter-basins fractionation contrasts with *DCo* known to be stabilized in solution by strong complexation with organic ligands (conditional stability constant $K_{CoL} > 10^{13}$) (Saito and Moffett, 2001; Saito et al., 2004, 2005, 2010; Bown et al., 2012a). On the other hand, other processes, such as mixing of water masses, have also been suggested to account for the decrease of *DCo* along the circulation in poor-oxygenated waters (Noble et al., 2012). We further investigated the behavior of *DCo* along the water-masses transportation in the deep and intermediate western Atlantic, which is conceptualized in Fig. 7.

4.2.1 Transportation in bottom waters within the core of AABW

The Antarctic Bottom Waters spread northward with a transport of 3–5 Sv (where 1 Sv is equal to $10^6 \text{ m}^3 \text{ s}^{-1}$) following the topography, in an opposite direction to the overlaying NADW (Tomczak and Godfrey, 2003). The mean *DCo* concentration in the AABW below 4000 m is 41.75 ± 5.3 pM along the whole transect ($n = 87$), but higher *DCo* levels are found in the older AABW flowing in the Northern Hemisphere than in the more recently formed AABW flowing in the Southern Hemisphere (mean values of 44.52 ± 4.8 pM, $n = 42$; and 39.29 ± 4.4 pM, $n = 45$, respectively). At the same southern latitudes, *DCo* concentrations were similar to those reported in the core of the recently formed AABW, but in the eastern Atlantic Ocean (Bown et al., 2011; Table 2). Similar northward bottom enrichment of *DCo* in the core of AABW (see Supplement Fig. S1a), together with water mass

pathway and aging, has also been observed in the eastern Atlantic sector (Bown et al., 2011). Enrichment due to mixing of the AABW with the NADW in the subarctic basin is unlikely since *DCo* display similar concentrations in the cores of these two water masses (Table 2). Bottom enrichment due to resuspension of abyssal sediments and their dissolution during AABW transportation is more likely to account for the northward increase of *DCo*. Such enrichment of *DCo* in waters following contact with basaltic sediments has recently been highlighted in a study on the Kerguelen Plateau (Bown et al., 2012b). The significant increase of *PCo* observed close to the seafloor in the Northern Hemisphere (Fig. 5), rising up to 30% of the total cobalt concentration at 34° N , also suggested that sediment resuspension could be significant. This is further supported by the strong signal of high dissolved aluminium concentrations observed in the bottom waters of the northern section ($40\text{--}50^\circ \text{ N}$) (R. Midagg, NIOZ, personal communication, 2014). Additionally, the concomitant increase of *PCo* and transmissometry near the seafloor (data not shown) strongly suggested benthic remobilization of cobalt. Finally, there was no record of high *DCo* at the bottom of the Mid-Atlantic Ridge (Fig. 4a), suggesting that hydrothermal activity may not be acting as a significant source of *DCo*, as previously thought (Bown et al., 2011).

4.2.2 Transportation within the core of the NADW

Comparison of the *DCo* concentrations recorded in this study in the cores of the NEADW, NADW and D-AAIW with those reported in the southeastern Atlantic (Bown et al., 2011) shows an excellent agreement (Table 2). This comparison suggests that *DCo* may not be scavenged during zonal (eastward) transportation across the South Atlantic at intermediate and deep depths.

To investigate the meridional transportation of *DCo* across the deep western Atlantic Ocean in the core of the NADW, this water mass was characterized along its route southward with respect to its mean *DCo* concentrations at three different potential density anomaly, corresponding to its center ($\sigma_0 = 27.85 \pm 0.02$), its upper-limit where the NADW interacts with intermediate waters (e.g., $\sigma_0 = 27.65 \pm 0.1$), and its lower-limit in contact with bottom waters (e.g., $\sigma_0 = 27.89 \pm 0.015$) (see Supplement Fig. S1b). No significant variations were observed along these isoclines from the subarctic gyre to the equatorial area (e.g., *DCo* = 68.7 ± 6 pM, $n = 62$ at $\sigma_0 = 27.65$; 58.8 ± 3 pM, $n = 19$ at $\sigma_0 = 27.85$; 56.9 ± 7 pM, $n = 21$ at $\sigma_0 = 27.89$), suggesting conservative behavior of *DCo* in the NADW. Around the Equator, *DCo* concentration increased at two potential densities (71.4 ± 4.4 pM, $n = 10$ at $\sigma_0 = 27.65$; 62.6 ± 5 pM, $n = 14$ at $\sigma_0 = 27.85$) and decreased in the denser waters (*DCo* = 51.9 ± 8 pM, $n = 20$ at $\sigma_0 = 27.89$). There was no variation of *PCo* in this area at $\sigma_0 = 27.65$ and $\sigma_0 = 27.85$, and there was an increase of *PCo* at $\sigma_0 = 27.89$ (by 4.6 pM), all suggesting that remineralization of *PCo* could not be

Fig. 7. Conceptual schema of the DCo transportation along the large-scale circulation in the intermediate and deep western Atlantic Ocean.

Table 2. Averaged dissolved cobalt concentration (DCo) and standard deviation (SD) obtained in the different water masses encountered along the western Atlantic GEOTRACES-A02 section: the Northeast Atlantic Deep Water (NEADW), Labrador Sea Water (LSW), North Atlantic Deep Water (NADW), Western Atlantic Central Waters (W-ACW), Northwest Antarctic Bottom Water (NW-AABW), Southwest Antarctic Bottom Water (SW-AABW), Upper Circumpolar Deep Water (UCDW) and Drake Antarctic Intermediate Water (D-AAIW).

Water mass	DCo (pM) (Others)	DCo (pM) (This study)	SD (pM) (This study)	n (This study)
NEADW	53.9 ± 3.3^a	54.3	2.7	24
LSW		68.8	3.2	38
NADW	59.2 ± 2.05^a 70 ± 11^b	61.8	8.2	204
W-ACW	79 ± 11^b	71	9	41
NW-AABW		44.52	4.8	42
SW-AABW	40.0 ± 2.49^a 42 ± 12^b	39.29	4.4	45
UCDW	57.3 ± 2.18^a	58.7	3.9	4
D-AAIW	55.8 ± 3.68^a	53.7	4.3	11

^a from Bown et al. (2011). ^b from Noble et al. (2012).

directly related to the increases in DCo at those depths. Hence, the enrichment of DCo in the upper NADW may be more likely due to mixing with the overlying Western Atlantic Central Water (W-ACW), containing relatively high DCo concentrations (> 85 pM).

Southward, the concentrations of DCo and PCo in the three layers were similar to those observed in the equatorial area until 20° S ($\sigma_0 = 27.88$) or 30° S (along $\sigma_0 = 27.65$ and $\sigma_0 = 27.85$) (see Supplement Fig. S1b), again suggesting that DCo behaved conservatively at those southward latitudes. However, south of 20° S, a decrease of DCo

concentrations was observed along the three isoclines (see Supplement Fig. S1b). This decrease was more pronounced at the upper and lower limits than in the center of the NADW (e.g., the difference of concentrations between the North and the South Atlantic are $\Delta DCo_{\sigma_0=27.65} = -11.5$ pM; $\Delta DCo_{\sigma_0=27.85} = +1.5$ pM; $\Delta DCo_{\sigma_0=27.89} = -10.3$ pM). There was no variation in the PCo concentrations associated with the decreases in DCo at the three depths (Fig. 4b), again suggesting that scavenging of DCo onto particles is not likely. Mixing and dilution of the NADW with the overlying waters (D-AAIW in the upper limit and AABW in the lower

layer) containing lower concentrations of DCo (Table 2) are thus more likely to explain the DCo decrease. Since mixing is stronger at the edges of the water masses, the center of the NADW would be less impacted by such mixing effect.

We further investigated the effect of water-masses mixing on the southward DCo gradients along the NADW by calculating the DCo concentrations resulting from the dilution of intermediate and deep water masses (Fig. 7). In the northern section, the NADW is formed by mixing 5 Sv of LSW with a mean DCo concentration of 68.8 ± 3.17 pM ($n = 38$; Table 2), with 10 Sv of NEADW with a mean DCo concentration of 54.3 ± 2.69 pM ($n = 24$; Table 2) (Tomczak and Godfrey, 2003). The resulting theoretical concentration of DCo of 59.13 pM compared perfectly with the mean DCo concentration observed in the NADW (61.4 ± 7.8 , $n = 204$; Table 2). In the equatorial area, the mixing of 15 Sv of the NADW with the 4 Sv of the W-ACW (Schmitz, 1995) leads to a theoretical DCo concentration of 66.1 pM, which is in excellent agreement with our measurements in this area ($DCo = 65.3 \pm 7$, $n = 43$). The slight increase observed in the DCo concentration of the NADW in this area can thus be due to mixing between the high DCo concentrations of the W-ACW and the NADW. The vertical mixing occurs through internal waves that can provide a mix of more than half of the NADW (up to 8 Sv) (Webb and Sugimoto, 2001). Along the southward flow of the NADW in the Southern Hemisphere, the DCo concentrations are higher than in the north ($DCo = 63.7 \pm 7$ pM, $n = 23$) until 30° S, beyond which a strong decrease is observed ($DCo = 54.6 \pm 7$ pM, $n = 45$). Here, the penetration of the 2.7 Sv of D-AAIW (You, 2002) in the intermediate ocean, along with the 5 Sv of AABW in the deep sea (Tomczak and Godfrey, 2003), leads to a theoretical DCo concentration of 54 pM in the NADW, which is in excellent agreement with the concentration we measured in the NADW for this area (54.3 ± 6.6 pM, $n = 41$). Thus, mixing with overlaying water masses seems to control the concentrations of DCo along the circulation pathway of the NADW from the subarctic gyre to the south-western Atlantic, rather than scavenging processes. The lack of scavenging has previously been suggested in the central Atlantic (Noble et al., 2012) and in the Ross Sea (Saito et al., 2010). Here we further support that dissolved cobalt would behave conservatively in the deep western Atlantic Ocean along the thermohaline circulation. In turn, the apparent scavenged profile observed in the southern part of the section (SAW) resulted from the incursion of DCo -depleted waters at the bottom of the ocean (AABW) and D-AAIW in intermediate waters.

4.2.3 Temporal variation in the Subarctic gyre

Resampling of the subarctic gyre after 2 years showed that the DCo concentration increased by 20.5 ± 5 pM in the NEADW below 3000 m when comparing station 5c of leg 4 (2012) with the stations 8 and 11 of leg 1 (2010) at about 51° N (Fig. 4a). Integrated on the thickness of the

NEADW (1250 m), this increase corresponded to about 25.6 ± 6.3 $\mu\text{mol m}^{-2}$. Associated with these relatively high DCo concentrations, relatively high PCo concentrations were also observed below 3000 m depth ($PCo > 5$ pM; Figs. 4b and 5d). The transit time of the NEADW to the latitude where the increase of DCo was detected is estimated to be around 2 years (Fine et al., 2001). Two possible hypotheses could be invoked to explain this anomaly observed at this location: (i) intensive sediments input in the NEADW through resuspension and dissolution, and/or diffusive processes during its circulation above the seafloor; and (ii) strong external input of cobalt to the Arctic surface waters transferred to the deep ocean by the formation of the NADW and its transportation through the deep large scale circulation.

Considering an input of DCo from dissolution of basalt or granite rocks of 0.054 ± 0.014 to $2.00 \pm 0.22 \times 10^{-11}$ $\text{mol m}^{-2} \text{d}^{-1}$ (Hausrath et al., 2009) and assuming this input would be continuous during the transit of the NEADW, the maximum cumulative input after two years of transit would be 14.6 nmol m^{-2} , which is three orders of magnitude lower than the excess observed. On the other hand, when considering a diffusive flux of Co from basalt of 31.1 $\text{nmol m}^{-2} \text{d}^{-1}$ estimated on the eastern Kerguelen Plateau (Bown et al., 2012a) and assuming a cumulative effect along the transportation of the water masses, the input would be 22.7 $\mu\text{mol m}^{-2}$, in the range of the excess in DCo observed at station 5c. However, the relatively poor-oxygenated waters ($O_2 < 200$ μM) flowing along the Kerguelen eastern slope coupled to a relative high slope current (0.08 cm s^{-1}) could have enhanced sediment resuspension (Bown et al., 2012b) and makes the comparison with our rather well ventilated bottom waters ($O_2 > 270$ μM) difficult. Furthermore, if sediment resuspension and dissolution would have caused the DCo anomaly, an increase in DCo along the pathway of the NEADW would be expected; however, this was not observed (Fig. 4a). Therefore, it is unlikely that the benthic input of DCo would cause the enhanced DCo concentrations that we observed in the core of the NEADW in 2012.

In April–May 2010 the Icelandic volcano Eyjafjallajökull erupted in the Arctic. The NEADW that forms in the Arctic transited for 2 years to reach the latitude where the excess of DCo was observed two years after the eruption in 2012 (Fine et al., 2002). It is thus conceivable that the DCo enrichment could be related to the input of these volcanic ashes and its advection by the NEADW. Volcanic ash emissions and subsequent deposition to the surface ocean have been reported to be a source of Co to the ocean (Frogner et al., 2001). Most of the ash deposition occurred close to the vent, with 98 % of the tephra being transported less than 600–700 km from the source, and then decreasing exponentially (Gudmundsson et al., 2012). Using an ash deposition model and the mean bulk density determined by Gudmundsson et al. (2012), we estimated an ash input of $1.68 \pm 0.7 \times 10^{14}$ g of tephra in the first

$9 \times 10^4 \text{ km}^2$ around Iceland, where the NEADW is formed. Using this input and a cumulative release of 8.76 nmol of DCo per gram of similar Iceland tephra (calculated after 1.5 h of release from Frogner, 2001), the input of DCo is thus estimated at around $16.3 \pm 6.3 \mu\text{mol m}^{-2}$ DCo in this area. Reported to the top 100 m, it represents an input of DCo of $163 \pm 63 \text{ pM}$, which is at least 1.5 and up to 2.5 times the concentration observed in upper 100 m at similar latitudes in the western subarctic gyre ($DCo_{f100m} = 67.2 \pm 2 \text{ pM}$), and much higher than the excess of DCo observed southward two years later ($20.5 \pm 5 \text{ pmol}$). Similarly, it has been shown that the 2010 Icelandic eruption had significantly enhanced iron concentrations in surface waters of the Arctic Sea, locally increasing by a factor 2.5 the iron concentration in solution even 6 days after the ash deposition (Achterberg et al., 2013). Furthermore, the mean input of DCo we estimated from the volcanic ashes ($16.3 \pm 6.3 \mu\text{mol m}^{-2}$) was in the same order of magnitude than the excess of DCo we measured two years later ($25.6 \pm 6.3 \mu\text{mol m}^{-2}$). These observations strongly suggested that the volcanic eruption was a source of DCo that has been advected in the core of the NADW. Because of the quick release of Co from the ash (Frogner et al., 2001), and probably because of the short residence time of these particles in the surface waters, it is possible that most of the input of DCo occurred under the ash plume. Its advection by the NADW then enhanced the concentration of DCo far away from the eruption, similarly to the advection of DCo from continental margins (Bown et al., 2011).

4.2.4 The incursion of the Atlantic Central Waters

The highest concentrations of DCo observed at intermediate depths in the equatorial area of the section were found in the core of the Atlantic Central Waters (ACW) that originate from the eastern Atlantic (Poole and Tomczak, 1999), and those DCo maxima correlated with the O_2 minimum (Figs. 2c, 4a and 5c). Actually, the incursion of the ACW constituted the major reservoir of DCo in the western Atlantic between the equatorial domain and the Caribbean basin (Fig. 4a). At these latitudes but in the eastern Atlantic, the O_2 depletion (Tomczak and Godfrey, 2003) and the DCo concentrations ($> 150 \text{ pM}$; Noble et al., 2012) are even higher in the ACW compared to the western Atlantic, suggesting zonal westward transportation and decrease of DCo across the central Atlantic ocean. Reductive dissolution in the poor-oxygenated waters, resuspension of particulate matter in the sediments along the shelves of the eastern Atlantic, and remineralization processes were suspected to cause the DCo enrichment in the ACW observed in the eastern Atlantic (Noble et al., 2012). A decrease in DCo concentrations was also observed along the transit of the ACW in the eastern basin, where scavenging could not be discerned from water masses mixing (Noble et al., 2012). Once reaching our meridian section, the concentration of DCo continued to decrease

northward in the flow of the ACW (from $93 \pm 1.3 \text{ pM}$ at 290 m, St. 15b to $73 \pm 0.6 \text{ pM}$ at 150 m, St. 36). Accompanying these decreases, there was no significant enrichment in PCo (Figs. 4b and 5f), suggesting that scavenging was negligible compared to mixing and vertical diffusion. As discussed above, mixing processes with the NADW can contribute to the decrease in the DCo concentrations along the westward transportation of the ACW. Furthermore, using the mean decrease of 15 nmol m^{-3} of DCo concentrations integrated into the W-ACW from St. 15b ($9^\circ \text{ S } 28^\circ \text{ W}$) to St. 36 ($8^\circ \text{ N } 49^\circ \text{ W}$) and considering the 4 Sv introduced by the ACW in this area (Schmitz, 1995), we estimated a decrease rate of DCo of about $5.2 \pm 0.5 \times 10^3 \text{ mol d}^{-1}$ due to the spread of the ACW northward. Reported to the surface of $2 \times 10^6 \text{ km}^2$ occupied by the ACW between 9° S and 8° N in the western Atlantic, this decrease rate corresponded to $2.6 \pm 0.25 \text{ nmol m}^{-2} \text{ d}^{-1}$. This zonal decrease rate compared well with the one we estimated between 10° E and 30° W using published DCo values for the eastern area (Noble et al., 2012). Indeed, we estimated a decrease in DCo concentrations of $56 \pm 14.8 \text{ nmol m}^{-3}$ across the central Atlantic Ocean ($10 \times 10^6 \text{ km}^2$), which corresponded to a decrease rate of $1.93 \pm 0.5 \text{ nmol m}^{-2} \text{ d}^{-1}$ when considering the ACW flow rate. In addition to dilution of the ACW, we suggest hereafter that the decreases of DCo can also be partially caused by vertical diffusion and advection of DCo to the surface waters, especially close to the equatorial currents where frontal systems and high turbulence were observed.

4.3 Remineralization and decoupling of the cobalt and phosphate relationship in the intermediate western Atlantic

4.3.1 Remineralization of cobalt in the Atlantic Central Waters

The highest DCo concentrations recorded along the section were observed in the ACW (Fig. 4a marked by the lowest concentrations of O_2 (Fig. 2c)). Hence, we estimated the portion of DCo resulting from cumulative remineralization in the ACW by using the apparent oxygen utilization (AOU). The AOU represents the integrated oxygen consumption by heterotrophic bacteria in the breakdown of organic matter and it is computed as the difference between the oxygen saturation concentration, which depends on thermohaline properties (Weiss, 1970), and the observed oxygen concentration. The significant correlation between AOU and DCo recorded in these waters (Fig. 8) strongly suggests that remineralization was driving the internal cycle of cobalt in these intermediate waters. Other studies have also reported relatively high DCo concentrations in low-oxygenated waters (Saito et al., 2004; Pohl et al., 2011; Noble et al., 2012). This relationship is used to estimate the concentration of DCo due to the cumulative remineralization in the ACW ($[DCo]_{\text{remineralization}}$, Eq. 1), and its proportion compared

Fig. 8. Relationship among the concentrations of dissolved cobalt (DCo) and the apparent oxygen utilization (AOU) in the intermediate waters of the equatorial area (150–750 m).

to the recorded concentration of DCo ($\%DCo_{\text{remineralized}}$, Eq. 2), as follows:

$$[DCo]_{\text{remineralization}} = (R_{Co:P} \times R_{P:O_2} \times AOU) \quad (1)$$

$$\%DCo_{\text{remineralized}} = 100 \times [DCo]_{\text{remineralization}} / [DCo]_{\text{observed}}, \quad (2)$$

where $R_{Co:P}$ is the stoichiometric Co : P ratio recorded in the surface waters of the equatorial area (with an average value of $27 \times 10^{-6} \text{ MM}^{-1}$; Dulaquais et al., 2014), and $R_{P:O_2}$ is the stoichiometric ratio between phosphate production and oxygen consumption (e.g., $R_{P:O_2} = 1/170 \text{ MM}^{-1}$; Matear and Hirst, 2003; Oschlies et al., 2008; Krishna-Murty et al., 2009).

The concentration of DCo due to remineralization was thus estimated at about $23 \pm 5 \text{ pM}$ in the western ACW between 150 and 800 m, representing 32 % of the DCo measured ($DCo_{f150-800\text{m}} = 71 \pm 9 \text{ pM}$). In its layer fed by the central South Equatorial Current (CSEC, 400–800 m), the cumulative remineralized DCo could be even higher, representing up to 37 % of DCo (Table 3). If this remineralized DCo was only supplied by the transportation through the CSEC from the eastern basin, this proportion should be greater in the eastern central Atlantic where dilution with NADW does not affect this water mass yet. But we estimated a similar proportion in the eastern Atlantic ($\%DCo_{\text{remineralized}} = 38 \pm 5 \%$) by using the DCo data set of Noble et al. (2012). This result suggested that the DCo provided by remineralization in the west equatorial Atlantic is likely a combination of a westward transportation of the DCo remineralized in the eastern Atlantic basin, the cumulative remineralization along the transportation of ACW in these O_2 depleted waters, and the mixing between NADW and ACW across the equatorial Atlantic and in the western basin.

4.3.2 Decoupling of the relationship between cobalt and phosphate

Several studies have shown that the biological utilization of DCo can be proportional to that of phosphate (P) in the surface waters of oligotrophic provinces (Saito et al., 2004, 2010; Jakuba et al., 2008; Noble et al., 2008; Bown et al., 2011). However, the lower apparent remineralization of DCo compared to P in intermediate and deep waters described by Bown et al. (2011) can suggest a decoupling between DCo and P in deeper waters. In our study, the absence of a significant correlation between DCo and P in intermediate and deep waters along the section ($R^2 < 0.1$, $n = 446$) further supported a decoupling between DCo and P in deep waters. Furthermore, the overall lower $DCo:P$ ratios observed in deep waters compared to the surface (data not shown) and the increase with depth of the Co : P ratio in the particles (Sherrill and Boyle, 1992; Table 3) both suggested that the decoupling can be either due to the preferential remineralization of P relative to Co, or to the preferential scavenging of DCo . However, our measurements shown that PCo concentrations were not increasing with depth but instead they were rather decreasing (Table 3), strongly suggesting that scavenging of DCo could be negligible. Hence, we further investigated the impact of the remineralization on the decoupling between DCo and P in the equatorial area where the OMZ was located and where ACW dispatched the highest DCo concentrations recorded along the section. The proportion of P due to the cumulative remineralization ($\%P_{\text{remineralized}}$) was thus estimated according to

$$\%P_{\text{remineralized}} = 100 \times (R_{P:O_2} \times AOU) / [P]_{\text{observed}}. \quad (3)$$

In this area, the proportion of P and Co produced by the cumulative remineralization was estimated in the surface layer mainly impacted by the geostrophic currents (0–150 m), the upper layer of the ACW which was influenced by the North Brazil Undercurrent, the equatorial and central branches of the South Equatorial Current, all forming the North Brazil Current at these depths (150–400 m), and the lower layer of the ACW mostly fed by the CSEC (400–800 m). It shown that the proportion of P provided by cumulative remineralization increased by a factor 7.4 between the surface layer and upper-ACW, whereas this increase was much lower for DCo (factor 1.5) (Table 3). This result suggested that the remineralization of P and DCo was not proportional in intermediate waters, and further supported the hypothesis that the preferential remineralization of P relative to DCo can largely cause the decoupling in deeper waters. Furthermore, the strongest remineralization of DCo that occurred deeper than that of P in the core of the lower-ACW (Table 3) may also lead to the decoupling between the deep cycles of DCo and P. Determination of the particles composition in Co and P would further help in understanding the processes involved in this decoupling.

Table 3. Mean dissolved cobalt concentration ($D\text{Co}$; pM), mean apparent particulate cobalt concentration ($P\text{Co}$; pM), and percentages of dissolved cobalt and phosphate produced by cumulative remineralization (respectively $D\text{Co}_{\text{rem}}$ and P_{rem} ; %) calculated in the surface layer (0–150 m), the upper layer of Atlantic Central Waters (150–400 m) and the lower layer of Atlantic Central Waters (400–800 m) between 10° S and 10° N (see text for definitions and calculation). The particulate ratios of Co : P ($(\text{Co}/\text{P})_{\text{in particles}}$; $\mu\text{M M}^{-1}$) recorded in the western Atlantic (Sherrell and Boyle, 1992) are also indicated for comparison. Errors are given as standard deviation from averaged values.

Depth (m)	$D\text{Co}_0$ (pM)	$P\text{Co}_0$ (pM)	$D\text{Co}_{\text{Rem}}$ (%)	P_{Rem} (%)	$(\text{Co}/\text{P})_{\text{in particles}}$ ($\mu\text{M M}^{-1}$)
0–150	32 ± 12 ($n = 37$)	4 ± 3 ($n = 13$)	22 ± 5	7 ± 1	403 ± 128

4.4 Physical processes impacting the distribution of dissolved cobalt in surface waters

4.4.1 Lateral advection in surface waters

The lateral advection from continental margin is thought to be a source of $D\text{Co}$ in the open surface ocean (Bown et al., 2011, 2012b; Noble et al., 2012), but this source is still largely uncharacterized. Therefore, we estimated the lateral advective $D\text{Co}$ supply in the surface waters of the section ($FDCo_{\text{adv}}$; Eq. 4) by calculating the local geostrophic velocities (u , v ; referenced 1000 dbars) based on sea level anomalies (SLA, www.aviso.oceanobs.com), and using the lateral $D\text{Co}$ gradients (x , y) integrated in the upper 150 m (z) between two nearby stations (a , b ; Eq. 5), using the following equations:

$$FDCo_{\text{adv}}(a) = \text{Grad}D\text{Co}_{(x,y)} \times \text{velocity}_a \times z \quad (4)$$

$$\text{Grad}D\text{Co}_{(x,y)} = [(D\text{Co}_{a \int 150\text{m}} - (D\text{Co}_{b \int 150\text{m}})]/d_{a \rightarrow b}, \quad (5)$$

where $D\text{Co}_{i \int 150\text{m}}$ is the mean $D\text{Co}$ concentration integrated over the upper 150 m at station (i); velocity_i is the lateral geostrophic velocity at station (i) integrated over the upper 150 m; z is equal to 150 m; and $d_{a \rightarrow b}$ is the distance between stations (a) and (b). A positive velocity is associated with a positive SLA and represents an advection from the considered station, and inversely for a negative velocity.

The dynamic structures with high lateral geostrophic velocities were generally observed in the frontal zones along the section (Table 4) and were associated with strong local currents (up to 20 cm s^{-1} , as observed at 5° N), whereas relatively low velocities were estimated in the center of each oceanic domain ($< 2 \text{ cm s}^{-1}$). However, isolated events such as eddies were also identified in the center of the NASG (Table 4). The estimations of the lateral advective fluxes of $D\text{Co}$ in surface waters showed variations of more than two orders of magnitude between the different areas (Table 4). For instance, in the center of the domains like at

the station BATS, the geostrophic velocities and lateral $D\text{Co}$ gradients were smooth, resulting in negligible lateral fluxes of $D\text{Co}$ ($-1 \text{ nmol m}^{-2} \text{ d}^{-1} < FDCo_{\text{adv}} < 1 \text{ nmol m}^{-2} \text{ d}^{-1}$). On the contrary, in the frontal zones where turbulence and significant lateral $D\text{Co}$ gradients can be observed, the lateral advection fluxes of $D\text{Co}$ were relatively high in surface waters (from $-61 \text{ nmol m}^{-2} \text{ d}^{-1}$ to $55 \text{ nmol m}^{-2} \text{ d}^{-1}$, Table 4).

The $D\text{Co}$ fluxes from lateral advection in surface waters can be important at a given station, but at the scale of a domain the impact was relatively limited, especially in the SASG. Indeed, at this scale the sum of the fluxes was low ($-3 \text{ nmol m}^{-2} \text{ d}^{-1} < FDCo < 3 \text{ nmol m}^{-2} \text{ d}^{-1}$). Nevertheless, the lateral advection within mesoscale structures, such as eddies, can be particularly important for the transportation of $D\text{Co}$ to interior basins, as it has been previously observed in the oligotrophic domain of the southeastern Atlantic where inputs of $D\text{Co}$ from continental margins were carried by Agulhas rings (Bown et al., 2011). Moreover, eddies can allow exchanges of $D\text{Co}$ between the different domains along the section, especially between the central Atlantic and the NASG through the equatorial current system, and between the SASG and the ECC through the MBC. Local turbulence associated with eddies can also induce local vertical advection (such as upwelling in the core of cyclonic eddies) as well as diffusion of $D\text{Co}$ from the intermediate waters. It has been shown that such physical processes can affect the vertical distribution of $D\text{Co}$ in surface waters (Noble et al., 2008; Shelley et al., 2012). All these direct and indirect effects make these dynamical structures sources or sinks of $D\text{Co}$ to the surface layer.

4.4.2 The vertical diffusion

The vertical diffusion has been described as an important source of iron (Fe) and other nutrients to the euphotic layer, sustaining phytoplankton development in Fe-depleted areas (Law et al., 2003; Croot et al., 2005; Blain et al., 2008). In the equatorial Atlantic this internal source of Fe may be even greater than the input of Fe from Saharan dust deposition

Table 4. Lateral gradient of dissolved cobalt ($\text{Grad } D\text{Co}_{f150\text{m}}$; $10^{-5} \text{ nmol m}^{-3} \text{ m}^{-1}$), and lateral advective fluxes of dissolved cobalt ($FDC\text{O}_{\text{adv}}$; $\text{nmol m}^{-2} \text{ d}^{-1}$) generated by local geostrophic lateral advection (Fw_{Geo} ; cm s^{-1}) are given in the upper 150 m for several sampling stations corresponding to key dynamical structures or domains.

(Rijkenberg et al., 2012). However, the importance of this supply for $D\text{Co}$ still has to be determined in the ocean. In the Southern Ocean and above the Kerguelen Islands the supply of $D\text{Co}$ to surface waters by vertical diffusion has been estimated to be negligible due to the small gradient in $D\text{Co}$ concentrations between the euphotic and mesopelagic layers caused by low biological assimilation of $D\text{Co}$ in these diatom-dominated waters (Bown et al., 2011, 2012b). By contrast, strong vertical gradients in $D\text{Co}$ concentrations between the surface and the nutricline were observed along the section in the western Atlantic Ocean, especially in the equatorial area (Fig. 5), allowing us to estimate this supply.

Briefly, the diffusion depends on the vertical gradient of $D\text{Co}$ concentrations, the diffusion coefficient (D_T) and the turbulent diffusivity coefficient (K_z). Whereas D_T is a physico-chemical property of the component within water (molecular property), the turbulent diffusivity coefficient is solely a property of the turbulent fluid. If the vertical gradient of concentrations ($\partial D\text{Co}/\partial z$) is much higher than the lateral gradients ($\partial \text{Co}/\partial x \approx \partial D\text{Co}/\partial y$), the lateral diffusion is considered negligible (see Tables 4 and 5). Furthermore, the values of K_z estimated along the section (M. Rijkenberg, NIOZ, personal communication, 2013) were three to six orders of magnitude higher than D_T ; hence, the molecular diffusivity was considered negligible. The highest values of K_z were found near frontal zones (M. Rijkenberg, NIOZ, personal communication, 2013) where strong geostrophic velocities were observed. One to two orders of magnitude lower turbulent diffusivities were found in the subtropical domains, coherent with lower turbulence of the water column and lower wind stress.

The intrusion of the ACW in the southern side of the equatorial area and its northward flow along the coast of South America through the Guyana and Caribbean Currents (Poole and Tomczak, 1999) transported relatively high $D\text{Co}$ within the mesopelagic layer and at the bottom of the euphotic layer (100–250 m) between 10° S and 10° N (Fig. 4a). Due

Table 5. Vertical dissolved cobalt gradient ($\Delta D\text{Co}/\Delta z_{100-300\text{m}}$; $\text{nmol m}^{-3} \text{ m}^{-1}$), mean $K_{z_{100-300\text{m}}}$ ($\text{cm}^2 \text{ s}^{-1}$) and vertical dissolved cobalt fluxes from the mesopelagic layer to the euphotic layer ($FDC\text{O}_{\text{vertical diff.}}$; $\text{nmol m}^{-2} \text{ d}^{-1}$) at few stations representative of the different areas crossed along the section (see text for the details of the calculations).

Location	$\Delta D\text{Co}/\Delta z_{100-300\text{m}}$	K_z	$FDC\text{O}_{\text{vertical diff.}}$

to relatively high $D\text{Co}$ assimilation in surface waters at these latitudes (Dulaquais et al., 2014), strong $D\text{Co}$ vertical gradients were generated between the surface and intermediate waters (Figs. 4a and 5). For instance, the $D\text{Co}$ vertical gradient can be as high as $0.31 \text{ nmol m}^{-3} \text{ m}^{-1}$ in the equatorial area at 9° S. By contrast, the vertical gradients are generally smooth in the subtropical domains and in the subarctic gyre ($<0.07 \text{ nmol m}^{-3} \text{ m}^{-1}$). Combining the vertical gradients with the K_z pattern, it is obvious that the vertical diffusion $D\text{Co}$ supply was expected to be higher in the frontal zones of the equatorial area than in the other domains. To further assess the role of the vertical diffusion on the distribution of $D\text{Co}$ in surface waters, we estimated the $D\text{Co}$ vertical diffusion flux ($FDC\text{O}_{\text{diffusion}}$) in the different domains using the following equation:

$$FDC\text{O}_{\text{diffusion}} = -(K_z + D_T) \times (\partial D\text{Co}/\partial z) \quad (6)$$

with $10^3 < (K_z/D_T) < 10^6$.

The $D\text{Co}$ supply to the euphotic layer by vertical diffusion (Table 5) varies by two orders of magnitude between the frontal zones (e.g., $7 \text{ nmol m}^{-2} \text{ d}^{-1}$ in the north subtropical

frontal zone) and the center of the subtropical domains (e.g., $> 0.07 \text{ nmol m}^{-2} \text{ d}^{-1}$ in the oligotrophic domains). In the frontal systems, the highest turbulence (Table 5) combined with a significant vertical gradient of DCo concentrations caused high vertical diffusion fluxes of DCo into the surface waters. In the equatorial area the high diffusive input of DCo was mainly due to high vertical gradients of DCo induced by the incursion of the eastern south ACW enriched in DCo . This input may well sustain the growth of the cyanobacteria present in the equatorial domain towards 15° N (Tovar-Sanchez et al., 2006). By contrast, this input kept relatively low in the oligotrophic domains mainly due to lower turbulent fluids. Therefore, the vertical diffusion did not appear to be the dominant flux to sustain the cyanobacteria population in the oligotrophic domains of the western Atlantic. However, in these subtropical areas, eddies that locally increase the turbulence and thus vertical advection/diffusion (Noble et al., 2008) added to external sources such as dust deposition or rivers discharge (Tovar-Sanchez et al., 2006; Dulaquais et al., 2014) may rather be invoked than isopycnal diffusion to respond to the absolute requirement of the dominant cyanobacteria for cobalt (Saito and Moffett, 2001).

5 Conclusions

Large-scale observation of the deep distribution of dissolved cobalt as first assessed in this work allowed to further understand the role of physical and remineralization processes in the deep cycle of cobalt. In deep waters, DCo behaves conservatively along water masses transportation through the western Atlantic. Mixing and dilution of deep water masses, rather than scavenging of DCo onto settling particles, generate the meridional decrease of DCo along the southward large-scale circulation in the deep western Atlantic. This finding contrasted with previous interpretations which suggested that DCo is scavenged along the thermohaline circulation explaining the deep inter-basins fractionation (Bruland and Lohan, 2003). In addition, the conservative behavior of DCo allowed the persistence of relatively high concentrations in the core of the LSW and low concentrations in the underlying AABW, hence generating the apparent scavenged profile of DCo observed in the deep waters of the western Atlantic. It also allowed large-scale transportation of external cobalt sources to interior basins, such as the 2010 Icelandic volcanic eruption, which was depicted by relatively high DCo concentrations in the core of the NEADW at 51° S . In addition, the DCo enriched intermediate waters can act as internal inputs of DCo into the surface waters through dynamic processes. Eddies and dynamical structures such as equatorial surface jets could play a major role in the fertilization of surface water in DCo through vertical diffusion and lateral advection. The input of DCo by the vertical diffusion is particularly enhanced in the equatorial domain where the incursion of the Atlantic Central Waters at intermediate

depths that transports high DCo concentrations compared to the surface, generating a strong vertical DCo gradient. However, these processes are still poorly constrained and may act as sinks as well; further work is required to better constrain these fluxes.

Next to physical processes, reductive processes – notably those linked to the oxygenation of the water masses – also play a major role in the deep cycle of DCo . The ACW characterized by relatively low O_2 indeed exhibited the highest DCo concentrations encountered along the section, hence constituting the major reservoir of DCo in the western Atlantic. The relatively low oxygenation of these waters may have promoted the stabilization of DCo in the westward flow of the ACW across the Atlantic Ocean, whereas physical processes did not prevent DCo to decrease along the route of these waters due to mixing and dilution with other water masses containing less DCo and to vertical diffusion to surface waters. In addition, the significant correlation between DCo concentrations and the apparent oxygen utilization found in these waters further indicated that remineralization (abiotic and biotic) was driving the internal cycle of cobalt in these intermediate waters. The remineralization of DCo was not proportional to that of phosphate in these intermediate waters, unlike the biological uptake of both DCo and P previously reported in oligotrophic surface waters (e.g., Saito et al., 2002; Noble et al., 2008; Bown et al., 2011). This decoupling leads to an enrichment of Co relative to P in the settling particles, mainly due to the preferential remineralization of P rather than a preferential scavenging of Co. Records of truly particulate cobalt will further help in revealing the role of particles in the deep cycle of cobalt.

Acknowledgements. We are indebted to the captains, officers and crew members of the R/V *Pelagia* and RRS *James Cook*: without their exceptional support, this large ocean section would not have been possible. We are most grateful to H. J. W. de Baar, the Coordinator of the Dutch Project, and to Loes Gerringa and Micha Rijkenberg, the Chief Scientists of the cruises. We warmly thank Jan van Ooijen, K. Bakker, E. van Weerlee, S. Ossebaar for the analyses of nutrients, as well as S. Ober, Martin Laan, Steven van Heuven, S. Asjes and L. Wuis for providing high quality CTD data. This investigation was supported by the GEOTRACES-GEOSECS revisited in the western Atlantic project coordinated by Marie Boye and funded by the French LEFE-CYBER National Program of the Institut National des Sciences de l'Univers (INSU). We also acknowledge the European COST-Action ES801 for funding a Short Term Scientific Mission to Gabriel Dulaquais to join the last cruise. The Université de Bretagne Occidentale (UBO) and the Région Bretagne are supporting the PhD fellowship of G. Dulaquais. This

investigation is a contribution to the international GEOTRACES program. The two referees, Johann Bown and Abigail Noble, are warmly acknowledged for their constructive remarks, which improved the manuscript.

Edited by: G. Herndl
