## Abstract

In this paper, we perform an experimental analysis of digital predistortion in the context of SOA based CO-OFDM systems for metropolitan/access networks. We conduct a comparative analysis of several pre-distorders including a novel structure called the Generalized Envelope Memory Polynomials.

## Index Terms

Digital predistortion, CO-OFDM, Semiconductor Optical Amplifier, linearization, experimental

## I. INTRODUCTION

Semiconductor Optical Amplifiers (SOAs) have been the object of recent research in optical communication systems for their reasonable cost, their ability for easy integration, and their wide optical bandwidth [1]. Similarly, Coherent Optical Orthogonal Frequency Division Multiplexing (CO-OFDM) systems are being explored notably since they can be easily implemented with the use of Digital Signal Processing (DSP) and they have capability for high spectral efficiency [2]. The combination of a non-constant envelope OFDM configuration and SOAs as amplifiers gives rise to nonlinearities. Digital predistortion (DPD) has been used in radio communications and most recently in photonics to counter these undesirable effects [3]. The present paper aims to provide further insight on the benefits of various predistorders through an experimental investigation.

## II. DIGITAL PREDISTORTION ALGORITHMS

Predistortion is based on the idea that when faced with the undesirable effects of a nonlinear function, one way to address it is to apply the inverse of that nonlinear function in order to cancel these effects. With low complexity being a crucial aspect in photonics, this paper chooses to deal with three simplified inspired versions of the Volterra Series predistorders [4] : the Memory Polynomials (MP), the Envelope Memory Polynomials (EMP), and the Generalized Memory Polynomials (GMP).

We propose a new memory polynomials DPD structure, the Generalized Envelope Memory Polynomials (GEMP), with the aim to provide an extra degree of freedom as is the case for the GMP but focusing solely on the signal's magnitude. The GEMP's mathematical expression is shown below:

$$y_{GEMP}(n) = x(n) \left( c_0 + \sum_{k=1}^{K_a} \sum_{l=0}^{L_a-1} a_{kl} |x(n-l)|^k + \sum_{p=1}^{K_b} \sum_{q=1}^{K_c} \sum_{m=1}^{M_b} \sum_{l=0}^{L_b-1} b_{pqml} |x(n-l)|^p \cdot |x(n-l-m)|^q \right) \quad (1)$$

The added value of the GEMP is that its use can be extended to other scenarios such as intensity-modulation/direct-detection. To find the appropriate structural parameters without performing an exhaustive search, this paper uses the Hill-Climbing heuristic [5]. The predistorders' coefficients are estimated using least squares approximation.

## III. EXPERIMENTAL SETUP

The experimental setup used for this paper is depicted in Fig. 1. The input bit stream goes through a 4-QAM modulation. The 4-QAM symbols are coded into OFDM frames with a bandwidth of 8 GHz consisting of 128 subcarriers. The effective data rate in this case is 11.12 Gbit/s. Some hard-clipping at a 6 dB ratio is done on the time signal before being sent into the Keysight M8195A Arbitrary Waveform Generator (AWG) through a VISA connection. The 32 GSa/s digital-to-analog converters of the AWG have a resolution of 8 bits. The electro-optical conversion is done with the MXIQR-LN-30 optical

modulator that has a  $V_{\pi}$  of 5.4 V and the Keysight N4391A Optical Modulation Analyzer (OMA) local oscillator operating at 1540 nm with a laser linewidth of 100 kHz. The IQ modulator's operating point is stabilized via the MBC-IQ-LAB-A1 bias controller. The booster amplifier is a 750  $\mu\text{m}$  INPHENIX-IPAD1501 SOA with a gain of 17 dB, a noise figure of 9 dB, and a supplied bias current of 240 mA. The OMA performs the opto-electronic conversion with the 40 GSa/s analog-to-digital converters at a resolution of 8 bits, then sends the signal back into the computer by using the .NET interface. At the receiver, a lowpass filter with a 8.8 GHz bandwidth is applied to reduce out-band noise. Then, the signal goes through synchronization, equalization, phase and amplitude tracking, and demodulation. For the purposes of this paper, the fiber is not included as the focus is to reduce the nonlinearities caused by the SOA at the emitter side.

IV. RESULTS

The results shown in this section were obtained by identifying the predistorders (MP, EMP, GMP, and GEMP) at different input powers of the SOA then validating the DPD by sending 32 frames at that same input power. The input power into the SOA is measured by taking the power going into the OMA in an optical back-to-back setting. Fig. 2a displays the mean Error Vector Magnitude (EVM) averaged from 5 different measurements. The aim in terms of EVM should be a limit of 30% for the 4-QAM case [6]. It can be inferred that by using DPD the input power into the SOA can be increased from -15.75 dBm (no DPD) to -14 dBm (MP) and -13 dBm (EMP, GMP, and GEMP) while still meeting the EVM requirements. This corresponds to an increase in reach of 8.75 km (MP) and 13.75 km (EMP, GMP, and GEMP) for a single-mode fiber. As input power increases, the gain in performance from DPD becomes more apparent. Fig. 2b provides the constellation of the

Fig. 2: (a) Error Vector Magnitude and (b) Constellation of the no DPD and GEMP cases at  $P_{ref} = -13$  dBm

no DPD and GEMP cases at  $P_{ref} = -13$  dBm. The color code is an indication of density with the darkest color being the lowest density and the lightest color corresponding to the highest density. Using GEMP as an example for a no DPD versus with DPD comparison, a brighter constellation signifies a better quality of transmission with DPD compared to without DPD.

## V. CONCLUSION

The mitigation of nonlinear impairments caused by a booster SOA in a CO-OFDM network application was investigated experimentally. The effect of DPD is obvious with EMP, GMP, and GEMP performing better than MP.
